Abstract. The shallower oxygen-poor water masses of the ocean confine a majority of the microbial communities that can produce up to 90 % of oceanic N₂. This effective N₂-yielding section encloses a suspended small-particle layer, inferred from particle backscattering (bₚ) measurements. It is thus hypothesized that this layer (hereafter, the bₚ-layer) is linked to microbial communities involved in N₂ yielding such as nitrate-reducing SAR11 as well as sulfur-oxidizing, anammox, and denitrifying bacteria – a hypothesis yet to be evaluated. Here, data collected by three BGC-Argo floats deployed in the Black Sea are used to investigate the origin of this bₚ-layer. To this end, we evaluate how the key drivers of N₂-yielding bacteria dynamics impact the vertical distribution of bₚ and the thickness of the bₚ-layer. In conjunction with published data on N₂ excess, our results suggest that the bₚ-layer is at least partially composed of the bacteria driving N₂ yielding for three main reasons: (1) strong correlations are recorded between bₚ and nitrate; (2) the top location of the bₚ-layer is driven by the ventilation of oxygen-rich subsurface waters, while its thickness is modulated by the amount of nitrate available to produce N₂; and (3) the maxima of both bₚ and N₂ excess coincide at the same isopycnals where bacteria involved in N₂ yielding co-exist. We thus advance that bₚ and O₂ can be exploited as a combined proxy to delineate the N₂-yielding section of the Black Sea. This proxy can potentially contribute to refining delineation of the effective N₂-yielding section of oxygen-deficient zones via data from the growing BGC-Argo float network.

1 Introduction

Oxygen-poor water masses (O₂ < 3 µM) host the microbial communities that produce between 20 % and 40 % of oceanic N₂ mainly via heterotrophic denitrification and anaerobic oxidation of ammonium (Gruber and Sarmiento, 1997; DeVries et al., 2013; Ward, 2013). The shallower oxygen-poor water masses (~ 50–200 m) are the most effective N₂-producing section because this is where the microbial communities that condition the process mainly develop and generate up to 90 % of the N₂ (Ward et al., 2009; Dalsgaard et al., 2012; Babbin et al., 2014). These microbial communities include nitrate-reducing SAR11 and anammox, denitrifying, and sulfur-oxidizing bacteria (e.g., Canfield et al., 2010; Ulloa et al., 2012; Ward, 2013; Tsementzi et al., 2016; Callbeck et al., 2018). It is thus important to unravel the biogeochemical parameters that trigger the accumulation of such bacteria in the ocean’s oxygen-poor water masses. This information is crucial for understanding and quantifying how bacterial biomass and related N₂-yielding bacteria can respond to the ongoing expansion of oceanic regions with low oxygen (Keeling and Garcia, 2002; Stramma et al., 2008; Helm et al., 2011; Schmidtko et al., 2017). Ultimately, greater accuracy in this domain can contribute to improving mechanistic predictions on how such expansion will affect the oceans’ role in driving the Earth’s climate by sequestering atmospheric carbon dioxide (e.g., Oschlies et al., 2018).

In oxygen-poor water masses, the biogeochemical factors that can affect the abundance of denitrifying and anammox bacteria are the levels of O₂, organic matter (OM), nitrate (NO₃⁻), ammonium (NH₄⁺), and hydrogen sulfide (H₂S) (Murray et al., 1995; Ward et al., 2008; Dalsgaard et al., 2014; Bristow et al., 2016). Therefore, to elucidate what trig-
gers the confinement of such bacteria, we need to investigate how the above biogeochemical factors drive their vertical distribution, with high temporal and vertical resolution. To this end, we should develop multidisciplinary approaches that allow us to permanently monitor the full range of biogeochemical variables of interest in oxygen-poor water masses.

Optical proxies of tiny particles can be applied as an alternative approach to assess the vertical distribution of N\textsubscript{2}-yielding microbial communities in oxygen-poor water masses (Naqvi et al., 1993). For instance, nitrate-reducing SAR11 and anammox, denitrifying, and sulfur-oxidizing bacteria are found as free-living bacteria (0.2–2 \textmu m) and can be associated with small suspended (> 2–30 \textmu m) and large sinking (> 30 \textmu m) particles (Fuchsman et al., 2011, 2012a, 2017; Ganesh et al., 2014, 2015). Therefore, particle backscattering (b\textsubscript{bp}), a proxy for particles in the ∼0.2–20 \textmu m size range (Stramski et al., 1999, 2004; Organelli et al., 2018), can serve to detect the presence of these free-living bacteria and those associated with small suspended particles.

Time series of b\textsubscript{bp} acquired by biogeochemical Argo (BGC-Argo) floats highlight the presence of a permanent layer of suspended small particles in shallower oxygen-poor water masses (b\textsubscript{bp}-layer) (Whitmire et al., 2009; Wojtasiewicz et al., 2020). It has been hypothesized that this b\textsubscript{bp}-layer is linked to N\textsubscript{2}-yielding microbial communities such as nitrate-reducing SAR11 and denitrifying, anammox, and sulfur-oxidizing bacteria. However, this hypothesis has not yet been clearly demonstrated. To address this, the first step is to evaluate (1) potential correlations between the biogeochemical factors that control the presence of the b\textsubscript{bp}-layer and such arrays of bacteria (O\textsubscript{2}, NO\textsubscript{3}\textsuperscript{−}, OM, H\textsubscript{2}S; Murray et al., 1995; Ward et al., 2008; Fuchsman et al., 2011; Ulloa et al., 2012; Dalsgaard et al., 2014; Bristow et al., 2016) and (2) the possible relationship between the b\textsubscript{bp}-layer and N\textsubscript{2} produced by microbial communities.

This first step is thus essential for identifying the origin of the b\textsubscript{bp}-layer and, ultimately, determining whether BGC-Argo observations of b\textsubscript{bp} can be implemented to delineate the oxygen-poor water masses where such bacteria are confined. The Black Sea appears a suitable area for probing into the origin of the b\textsubscript{bp}-layer in low-oxygen waters in this way. It is indeed a semi-enclosed basin with permanently low O\textsubscript{2} levels where N\textsubscript{2} production and related nitrate-reducing SAR11 and denitrifying and anammox bacteria are mainly confined within a well-defined oxygen-poor zone (Kuypers et al., 2003; Konovalov et al., 2005; Kirkpatrick et al., 2012). In addition, a permanent b\textsubscript{bp}-layer is a typical characteristic of this region, which is linked to such microbial communities and inorganic particles (Stanek et al., 2017, 2018; see details in Sect. 2).

The goal of our study is therefore to investigate the origin of the b\textsubscript{bp}-layer in the oxygen-poor waters of the Black Sea using data collected by BGC-Argo floats. More specifically, we aim to evaluate, within the oxygen-poor zone, how (1) two of the main factors (O\textsubscript{2} and NO\textsubscript{3}\textsuperscript{−}) that drive the dynamics of denitrifying and anammox bacteria impact the location and thickness of the b\textsubscript{bp}-layer, (2) NO\textsubscript{3}\textsuperscript{−} controls the vertical distribution of b\textsubscript{bp} within this layer, (3) temperature drives the formation of the b\textsubscript{bp}-layer and consumption rates of NO\textsubscript{3}\textsuperscript{−}, and (4) particle content inferred from b\textsubscript{bp} and N\textsubscript{2} produced by microbial communities can be at least qualitatively correlated. Ultimately, our findings allow us to infer that b\textsubscript{bp} can potentially be used to detect the presence of the microbial communities that drive N\textsubscript{2} production in oxygen-poor water masses – including nitrate-reducing SAR11 and sulfur-oxidizing, denitrifying, and anammox bacteria.

### 2 Background nature of the small particles contributing to the b\textsubscript{bp}-layer and their links with N\textsubscript{2} yielding

The oxygen-poor water masses of the Black Sea are characterized by a permanent layer of suspended small particles constituted of organic and inorganic particles (Murray et al., 1995; Kuypers et al., 2003; Konovalov et al., 2005; Kirkpatrick et al., 2012). In the oxygen-poor (O\textsubscript{2} < 3 \textmu m) section with detectable NO\textsubscript{3}\textsuperscript{−} and undetectable H\textsubscript{2}S levels, organic particles are mainly linked to microbial communities involved in the production of N\textsubscript{2}, and these include nitrate-reducing SAR11 and anammox, denitrifying, and sulfur-oxidizing bacteria (Kuypers et al., 2003; Lam et al., 2007; Yakushev et al., 2007; Fuchsman et al., 2011; Kirkpatrick et al., 2012). The first group listed, SAR11, provides NO\textsubscript{3}\textsuperscript{−} for N\textsubscript{2} yielding and makes the largest contribution (20 %–60 %) to N\textsubscript{2}-yielding bacteria biomass (Fuchsman et al., 2011, 2017; Tsementzi et al., 2016). Meanwhile, the second and third groups of bacteria make a smaller contribution to microbial biomass (∼10 %; e.g., Fuchsman et al., 2011, 2017) but dominate N\textsubscript{2} yielding via anammox (NO\textsubscript{3}\textsuperscript{−} + NH\textsubscript{4}\textsuperscript{+} → N\textsubscript{2} + 2H\textsubscript{2}O) and heterotrophic denitrification (NO\textsubscript{3}\textsuperscript{−} → NO\textsubscript{2}\textsuperscript{−} → N\textsubscript{2}O → N\textsubscript{2}) (Murray et al., 2005; Kirkpatrick et al., 2012; DeVries et al., 2013; Ward, 2013). The last group can potentially produce N\textsubscript{2} via autotrophic denitrification (e.g., 3H\textsubscript{2}S + 4NO\textsubscript{3}\textsuperscript{−} + 6OH\textsuperscript{−} → 3SO\textsubscript{4}\textsuperscript{2−} + 2N\textsubscript{2} + 6H\textsubscript{2}O; Sorokin, 2002; Konovalov et al., 2003; Yakushev et al., 2007). Finally, *Epsilonproteobacteria* are the major chemosynthetic bacteria that form organic particles in the sulfidic zone (e.g., oxygen-poor section with detectable sulfide levels (> 0.3 \textmu M) but undetectable NO\textsubscript{3}\textsuperscript{−}; Coban-Yildiz et al., 2006; Yilmaz et al., 2006; Grote et al., 2008; Canfield and Thamdrup, 2009; Glaubitz et al., 2010; Ediger et al., 2019). However, they can also be involved in the production of N\textsubscript{2} and linked formation of organic particles in the oxygen-poor section with detectable levels of sulfide and NO\textsubscript{3}\textsuperscript{−} (see Fig. 1, e.g., *Epsilonproteobacteria* Sulfurimonas acting as an autotrophic denitrifier; Glaubitz et al., 2010; Fuchsman et al., 2012b; Kirkpatrick et al., 2018).

The inorganic component is mainly due to sinking particles of manganese oxides (Mn, III, IV) that are formed due to
the oxidation of dissolved Mn (II, III) pumped from the sulfidic zone (e.g., \(2\text{Mn}^{2+}(l) + \text{O}_2 + 2\text{H}_2\text{O} \rightarrow \text{2MnO}_2(s) + 4\text{H}^+\); Konovalov et al., 2003; Clement et al., 2009; Dellwig et al., 2010). Ultimately, sinking particles of manganese oxides are dissolved back to Mn (II, III), mainly via chemosynthetic bacteria that drive sulfur reduction (e.g., \(\text{HS}^- + \text{MnO}_2(s) + 3\text{H}^+ \rightarrow \text{S}^0 + \text{Mn}^{2+}(l) + 2\text{H}_2\text{O}\); Jørgensen et al., 1991; Konovalov et al., 2003; Johnson, 2006; Yokushev et al., 2007; Fuchsmann et al., 2011; Stanev et al., 2018). Overall, these arrays of bacteria mediate the reactions described above by using electron acceptors according to the theoretical "electron tower" (e.g., \(\text{O}_2 \rightarrow \text{NO}_3^- \rightarrow \text{Mn(IV)} \rightarrow \text{Fe(III)} \rightarrow \text{SO}_4^{2-}\); Stumm and Morgan, 1970; Murray et al., 1995; Canfield and Thamdrup, 2009). Therefore, the vertical distributions of \(\text{NO}_3^-\), \(\text{N}_2\) excess, and content of small particles are driven by the reactions that occur in the chemical zones of oxygen-poor water masses (e.g., nitrogenous and manganous zones, which correspond to the sections where \(\text{NO}_3^-\) and Mn(IV), respectively, are predominantly used as electron acceptors; Murray et al., 1995; Konovalov et al., 2003; Yokushev et al., 2007; Canfield and Thamdrup, 2009; see also Sect. 4.2 and 4.3).

3 Methods

3.1 Bio-optical and physicochemical data measured by BGC-Argo floats

We used data collected by three BGC-Argo floats that profiled at a temporal resolution of 5–10 d in the first 1000 m depth of the Black Sea from December 2013 to July 2019 (Fig. 1). These floats – allocated World Meteorological Organization (WMO) numbers 6900807, 6901866, and 7900591 – collected 239, 301, and 518 vertical profiles, respectively. BGC-Argo float 6901866 was equipped with four sensors: (1) a SBE-41 CP conductivity–\(T\)–depth sensor (Sea-Bird Scientific), (2) an Aanderaa 4330 optode (serial number 1411, \(\text{O}_2\) range 0–1000 µM, with an accuracy of 1.5%), (3) a WET Labs ECO Triplet Puck, and (4) a Satlantic Submersible Ultraviolet Nitrate Analyzer (SUNA). These sensors measured upward profiles of (1) temperature (\(T\)), conductivity, and depth, (2) dissolved oxygen (\(\text{O}_2\)), (3) chlorophyll fluorescence, total optical backscattering (particles + pure seawater) at 700 nm, and fluorescence by colored dissolved organic matter, and (4) nitrate (\(\text{NO}_3^-\); detection limit of \(\sim 0.5\) µM with \(T\) / salinity correction processing) and bisulfide (\(\text{HS}^-\), detection limit of \(< 0.5\) µM; Stanev et al., 2018). Floats 6900807 and 7900591 were equipped with only the first three sensors.

Raw data of fluorescence and total backscattering were converted into chlorophyll concentration (chl) and particle backscattering \((b_{bp})\) following standard protocols, respectively (Schmechtig et al., 2014, 2015). Spike signals in vertical profiles of chl and \(b_{bp}\) and due to particle aggregates were removed by using a median filter with a window size of three data points (Briggs et al., 2011). \(\text{NO}_3^-\), \(\text{HS}^-\), and \(\text{O}_2\) data were processed following BGC-Argo protocols (Bittig and Körtzinger, 2015; Johnson et al., 2018; Thierry et al., 2018). Sampling regions covered by the three floats encompassed most of the Black Sea area (Fig. 1 and Appendix A). However, we only used data collected during periods without a clear injection of small particles derived from the productive layer and Bosporus plume (e.g., advection of water masses, Stanev et al., 2017). This restriction allowed us to focus on the in situ 1D processes driving local formation of the \(b_{bp}\)-layer, with minimal interference from any possible external sources of small particles.

We only describe the time series of data collected by float 6901866 because this was the only float carrying a \(\text{NO}_3^-/\text{HS}^-\) sensor. Data acquired by floats 6900807 and 7900591 are described in Appendix A and nevertheless used as complementary data to those of float 6901866 to corroborate (1) qualitative correlations between \(\text{O}_2\) levels and the location of the \(b_{bp}\)-layer and (2) consistency in the location of the \(b_{bp}\) maximum within the \(b_{bp}\)-layer.

3.2 Defining the oxygen-poor zone, mixed-layer depth, and productive layer

We used \(\text{O}_2\) and \(\text{NO}_3^-\) to, respectively, define the top and bottom isopycnals of the oxygen-poor zone where denitrifying and anammox bacteria are expected to be found. To set the top isopycnal, we applied an \(\text{O}_2\) threshold of \(< 3\) µM because denitrifying and anammox bacteria seem to tolerate \(\text{O}_2\) concentrations beneath this threshold (Jensen et al., 2008; Dalsgaard et al., 2014; Babbin et al., 2014). The bottom isopycnal was defined as the deepest isopycnal at which \(\text{NO}_3^-\) was detected by the SUNA sensor (0.23 ± 0.32 µM). \(\text{NO}_3^-\) was used to set this isopycnal because heterotrophic denitrification and subsequent reactions cannot occur without \(\text{NO}_3^-\) (Lam et al., 2009; Bristow et al., 2017). \(\text{HS}^-\) was not used to delimit the bottom of this zone because the maximum concentration of \(\text{HS}^-\) that denitrifying and anammox bacteria tolerate is not well established (Murray et al., 1995; Kirkpatrick et al., 2012; see also Sect. 4.1).

Mixed-layer depth (MLD) was computed as the depth at which density differed from 0.03 kg m\(^{-3}\) with respect to the density recorded at 1 m depth (de Boyer Montégut et al., 2004). We used chl to define the productive layer where living phytoplankton were present and producing particulate organic carbon. The base of this layer was set as the depth at which chl decreased below 0.25 mg m\(^{-3}\). This depth was used only as a reference to highlight the periods when surface-derived small particles were clearly injected into the oxygen-poor zone.
3.3 Complementary cruise data on $N_2$ excess and $NO_3^-$

Published data on $N_2$:Ar ratios and $NO_3^-$ collected in the southwest of the Black Sea in March 2005 (Fuchsman et al., 2008, 2019) were exploited to complement discussion of our results. $N_2$ produced by anaerobic microbial communities ($N_2$ excess, $\mu$M) was estimated from $N_2$:Ar ratios and argon concentrations at atmospheric saturation (Hamme and Emerson, 2004). $N_2$ excess data were used to (1) describe the oxygen-poor zone where $N_2$ is expected to be predominantly produced and (2) highlight qualitative correlations between $N_2$ excess, the location of the $b_{bp}$-layer, and vertical distribution of small particles within the $b_{bp}$-layer.

4 Results and discussion

4.1 Description of the oxygen-poor zone

The top and bottom of the oxygen-poor zone are located around isopycnals (mean ± standard deviation) 15.79 ± 0.23 and 16.30 ± 0.09 kg m$^{-3}$, respectively. The two isopycnals therefore delimit the oxygen-poor water masses where nitrate-reducing SAR11 and denitrifying, anammox, and sulfur-oxidizing bacteria are expected to be found (zone hereafter called the OP$_{DA}$, Fig. 2; Kuypers et al., 2003; Lam et al., 2007; Yakushev et al., 2007; Fuchsman et al., 2011; Kirkpatrick et al., 2012). The top location of the OP$_{DA}$ shows large spatial–temporal variability ranging between 80 and 180 m (or $\sigma_\theta$ between 15.5 and 15.9 kg m$^{-3}$, Fig. 2). Similarly, the OP$_{DA}$ thickness varies between 30 and 80 m, which corresponds to a $\sigma_\theta$ separation of $\sim$0.50 kg m$^{-3}$. The bottom of the OP$_{DA}$ is slightly sulfidic (HS$^-$ = 11.4 ± 3.53 $\mu$M, n = 86) and deeper than suggested (e.g., $\sigma_\theta$ = 16.20 kg m$^{-3}$ and H$_2$S ≤ 10 nM; Murray et al., 1995). However, our results coincide with the slightly sulfidic conditions of the deepest isopycnal at which anammox bacteria can still be recorded ($\sigma_\theta$ = 16.30 kg m$^{-3}$ and H$_2$S ≥ 10 $\mu$M; Kirkpatrick et al., 2012).

4.2 $NO_3^-$, $O_2$, and MnO$_2$ as key drivers of the thickness and location of the suspended small-particle layer

The permanent $b_{bp}$-layer is always confined within the two isopycnals that delimit the OP$_{DA}$ (Fig. 2). It follows that the thickness and top location of this layer demonstrate the same spatial and temporal variability as the one described for the OP$_{DA}$ (Fig. 2 and Appendix A). This correlation indicates that variations in the thickness and top location of the $b_{bp}$-layer are partially driven, respectively, by (1) the amount of $NO_3^-$ available to produce $N_2$ inside the OP$_{DA}$ via the set of bacteria communities involved and (2) downward ventilation of oxygen-rich subsurface waters (Fig. 2 and Appendix A).

$NO_3^-$ and $O_2$ are two of the key factors that modulate the presence of (1) denitrifying and anammox bacteria working in conjunction with nitrate-reducing SAR11 (Fuchsman et al., 2011; Ulloa et al., 2012; Tsementezi et al., 2016; Bristow et al., 2017), and probably with chemoautotrophic ammonia-oxidizing bacteria (in this case, only with anammox, e.g., $\gamma$-AOB; Ward and Kilpatrick, 1991; Lam et al., 2007), and (2) sulfur-oxidizing bacteria (e.g., SUP05 and potentially *Epsilonproteobacteria* Sulfurimonas; Canfield et al., 2010; Glaubitz et al., 2010; Fuchsman et al., 2011, 2012b; Ulloa et al., 2012; Kirkpatrick et al., 2018). Therefore, the results described above highlight that at least a fraction of the $b_{bp}$-layer should be due to this array of bacteria. This notion is supported by three main observations. Firstly, the top location of the $b_{bp}$-layer is driven by the intrusion of subsurface water masses ($S \leq 20.36 \pm 0.18$ psu) with $O_2$ concentrations above the levels tolerated by denitrifying and anammox bacteria ($O_2 \geq 3 \mu$M; Jensen et al., 2008; Babbie et al., 2014; Fig. 2). As a result, in regions where $O_2$ is ventilated to deeper water masses, the top location of the $b_{bp}$-layer is also deeper. The contrary is observed when $O_2$ ventilation is shallower (Fig. 2 and Appendix A). Secondly, nitrate-reducing SAR11 and denitrifying, anammox, and sulfur-oxidizing bacteria reside between isopycnals 15.60 and 16.30 kg m$^{-3}$ (Fuchsman et al., 2011, 2012a; Kirkpatrick et al., 2012), while the $b_{bp}$-layer is formed between isopycnals $\sim$15.79 and 16.30 kg m$^{-3}$. We can thus infer coexistence of such bacteria between the coincident isopycnals where the $b_{bp}$-layer is generated. Thirdly, $NO_3^-$ declines from around isopycnal 15.79 kg m$^{-3}$ to isopycnal 16.30 kg m$^{-3}$ due to the expected $N_2$ production via the microbial communities involved (Figs. 2–3 and Kirkpatrick et al., 2012).

The ventilation of subsurface $O_2$ is also key in driving the depth at which MnO$_2$ is formed ($O_2 \leq 3–5 \mu$M; Clement et al., 2009) and can thus contribute to setting the characteristics of the $b_{bp}$-layer via its subsequent accumulation and dissolution (Konovalov et al., 2003; Clement et al., 2009; Dellwig et al., 2010). Thus, in regions where subsurface $O_2$ (e.g., $O_2 \geq 3–5 \mu$M and $S \leq 20.36 \pm 0.18$ psu) is ventilated to deeper water masses, both the formation of MnO$_2$ and top location of the $b_{bp}$-layer can be expected to be deeper and vice versa (Fig. 2). Finally, the dissolution of MnO$_2$ should also influence the thickness of the $b_{bp}$-layer because it occurs just beneath the maxima of the optical particles inside this layer (Konovalov et al., 2006; see the explanation in Sect. 4.3).

Overall, the qualitative evidence presented above points out that particles of MnO$_2$ as well as nitrate-reducing SAR11 and denitrifying, anammox, and sulfur-oxidizing bacteria appear to define the characteristics of the $b_{bp}$-layer (Johnson, 2006; Konovalov et al., 2003; Fuchsman et al., 2011, 2012b; Staney et al., 2018). This observation leads us to argue, in the next section, that the $b_{bp}$-layer is partially composed of the main group of microbial communities involved in $N_2$ yielding as well as of MnO$_2$. 

Biogeosciences, 17, 6491–6505, 2020
4.3 Role of the removal rate of $\mathrm{NO}_3^-$, $\mathrm{MnO}_2$, and temperature in the vertical distribution of small particles

We propose that the removal rate of $\mathrm{NO}_3^-$ is a key driver of the vertical distribution of small particles and $\mathrm{N}_2$ excess within the $\mathrm{OP}_{\text{DA}}$. This is because the vertical profiles of small particles and of $\mathrm{N}_2$ excess are qualitatively similar, and both profiles are clearly related to the rate at which $\mathrm{NO}_3^-$ is removed from the $\mathrm{OP}_{\text{DA}}$ (Figs. 3–4). For instance, maxima of $\mathrm{N}_2$ excess and $b_{bp}$ coincide around isopycnal $16.11 \pm 0.11 \text{ kg m}^{-3}$ (Fig. 3; Konovalov et al., 2005; Fuchsmann et al., 2008, 2019). At this isopycnal, the mean concentration of $\mathrm{NO}_3^-$ is $1.19 \pm 0.53 \mu\text{M}$. We thus propose that this $\mathrm{NO}_3^-$ threshold value splits the $\mathrm{OP}_{\text{DA}}$ into two sub-zones with distinctive biogeochemical conditions (e.g., nitrogenous and manganous zones; Canfield and Thamdrup, 2009). Ultimately, these two different sets of conditions drive the rates at which $\mathrm{NO}_3^-$ and small particles are removed and formed within the $\mathrm{OP}_{\text{DA}}$, respectively (Fig. 3 and explanation below).

The first sub-zone is thus located between the top of the $\mathrm{OP}_{\text{DA}}$ ($\sigma_0 = 15.79 \text{ kg m}^{-3}$) and around isopycnal $16.11 \text{ kg m}^{-3}$. Here, removal rates of $\mathrm{NO}_3^-$ ($\leq 0.16 \pm 0.10 \mu\text{M m}^{-1}$, Fig. 4) are likely to be boosted by (1) high content of organic matter (dissolved organic carbon $= 122 \pm 9 \mu\text{M}$, Margolin et al., 2016) and $\mathrm{NO}_3^-$ ($\geq 1.19 \pm 0.53 \mu\text{M}$) and (2) $\mathrm{O}_2$ levels staying between a range that maintains the yielding of $\mathrm{N}_2$ ($0.24 \pm 0.04 \mu\text{M} \geq \mathrm{O}_2 \leq 2.8 \pm 0.14 \mu\text{M}$, $n = 100$, the means of the minima and maxima of $\mathrm{O}_2$, respectively, in the first sub-zone) and promotes the formation of $\mathrm{MnO}_2$ (e.g., maximum of Mn(II) oxidation is at $\mathrm{O}_2$ levels $\sim 0.2 \mu\text{M}$; Clement et al., 2009). Consequently, the formation of biogenic and inorganic small particles (and related $\mathrm{N}_2$ excess) increases from the top of the $\mathrm{OP}_{\text{DA}}$ to around isopycnal $16.11 \text{ kg m}^{-3}$ (Fig. 3). This hypothesis is (1) in part confirmed by significant and negative power-law correlations between the suspended small-particle content and $\mathrm{NO}_3^-$ in this sub-zone (Fig. 3) and is (2) in agreement with the progressive accumulation of $\mathrm{MnO}_2$ from around isopycnal $15.8 \text{ kg m}^{-3}$ to isopycnal $16.10 \text{ kg m}^{-3}$ (e.g., Konovalov et al., 2006).

The second sub-zone is located between isopycnal $16.11 \text{ kg m}^{-3}$ and the bottom of the $\mathrm{OP}_{\text{DA}}$ ($\sigma_0 = 16.30 \text{ kg m}^{-3}$, Fig. 3). Here, $\mathrm{NO}_3^-$ is low ($\leq 1.19 \pm 0.53 \mu\text{M}$) and $\mathrm{O}_2$ is relatively constant ($0.23 \pm 0.02 \mu\text{M}$, $n = 2284$; mean of $\mathrm{O}_2$ calculated in the second sub-zone for all profiles) or lower than the minimum of $\mathrm{O}_2$ recorded by this sensor ($0.22 \pm 0.02 \mu\text{M}$, $n = 1284$).
Figure 2. Time series of (a) salinity (S), (b) O$_2$, (c) NO$_3^-$, (d) log($b_{bp}$), and (e) HS$^-$. The blue lines in (a) and (b) indicate the mixed-layer depth. The red lines in (a), (b), and (d) show the base of the productive region. Isopycnals 15.79 and 16.30 kg m$^{-3}$ describe the top and bottom of the oxygen-poor zone (OP$_{DA}$), respectively. SU, A, W, and SP stand for summer, fall, winter, and spring, respectively. The colored horizontal line in (b) indicates the sampling site for a given date (Fig. 1). The horizontal white lines in (d) are the profiles used to (1) delimit the OP$_{DA}$ and (2) compute correlations between $b_{bp}$, NO$_3^-$, and $T$ within the OP$_{DA}$.

$n = 89$). These constant (or lower) levels of O$_2$ roughly correspond to those at which anammox and heterotrophic denitrification are inhibited by $\sim 50\%$ (0.21 and 0.81 µM, respectively; Dalsgaard et al., 2014). In addition, low levels of NO$_3^-$ necessarily promote the microbial use of Mn(IV) as an electron acceptor, ultimately dissolving the particles of MnO$_2$ into Mn(II) (e.g., manganous zone; Konovalov et al., 2003, 2005, 2006; Yakushev et al., 2007; Canfield and Thamdrup, 2009). As a result, this sub-zone exhibits a decline in removal rates of NO$_3^-$ ($-0.04 \pm 0.01$ µM m$^{-1}$, Fig. 4) along with inhibited formation of biogenic small particles and dissolution of MnO$_2$. Ultimately, both the content of small particles and related N$_2$ excess decrease from around isopycnal 16.11 kg m$^{-3}$ to the bottom of the OP$_{DA}$ (Fig. 3). These results are in agreement with (1) significant and positive exponential correlations computed between the small-particle content inferred from $b_{bp}$ and NO$_3^-$ within this sub-zone (Fig. 3) and (2) the overlap of nitorgenous and manganous zones in this sub-zone because the content of MnO$_2$ particles and dissolved Mn(II) concurrently declines and increases just beneath isopycnal 16.11 kg m$^{-3}$, respectively (e.g., Murray et al., 1995; Konovalov et al., 2003, 2005, 2006; Yakushev et al., 2007; Canfield and Thamdrup, 2009).

Strong-positive linear correlations are also recorded between $b_{bp}$ and $T$ in the first sub-zone of the OP$_{DA}$ (Fig. 4). This is likely to indicate that the formation of small particles is sensitive to very tiny increments in $T$ ($0.003 \pm 0.001$ °C m$^{-1}$, $n = 133$). We thus infer a tendency for the decline rates of NO$_3^-$ and related production of N$_2$ to increase with $T$. This hypothesis is at least partially supported by the significant correlation between NO$_3^-$ decline rates and $T$ increase rates in this sub-zone (Fig. 4). Within the second sub-zone, $T$ continues increasing while $b_{bp}$ decreases, likely due to inhibition of the formation of small particles for the reasons described above (Fig. 4). These observations suggest that the production of small particles is likely to have first- and second-order covariations with NO$_3^-$ and $T$, respectively – a likelihood backed up by a lack of correlation...
between NO$_3^-$ decline rates and $T$ increase rates in this sub-zone (Fig. 4). Finally, more information is needed to investigate the physical and/or biogeochemical processes driving the correlation between the increase rates of $T$ and declines rates of NO$_3^-$ in the first sub-zone. This is however beyond the scope of our study.

To summarize, BGC-Argo float data combined with a proxy of N$_2$ production suggest that in regions without the Bosporus plume influence, the $b_{bp}$-layer systematically tracks and delineates the effective N$_2$-yielding section independently of (1) the biogeochemical mechanisms driving N$_2$ yielding and (2) the contribution that MnO$_2$ and other microorganisms can be expected to make to the formation of the $b_{bp}$-layer (e.g., Lam et al., 2007; Fuchsman et al., 2011, 2012a; Kirkpatrick et al., 2018). It is thus finally inferred that this $b_{bp}$-layer is at least partially composed of the predominant anaerobic microbial communities involved in the production of N$_2$, such as nitrate-reducing SAR11 and anammox, denitrifying, and sulfur-oxidizing bacteria. These results also suggest that N$_2$ production rates can be highly variable in the Black Sea because the characteristics of the $b_{bp}$-layer show large spatial–temporal variations driven by changes in NO$_3^-$ and O$_2$ (Figs. 2 and 4). Finally, we propose that $b_{bp}$ and O$_2$ can be exploited as a combined proxy for defining the N$_2$-producing section of the oxygen-poor Black Sea. We consider that this combined proxy can delineate the top and base of this section by applying an O$_2$ threshold of 3.0 µM and the bottom isopycnal of the $b_{bp}$-layer, respectively. This section should thus be linked to free-living bacteria (0.2–2 µm) and those associated with small suspended
particles (> 2–20 µm) as well as to small inorganic particles (0.2–20 µm).

4.4 New perspectives for studying N₂ yielding in oxygen-deficient zones

The conclusions and inferences of this study, especially those related to the origin and drivers of the bₚ₃-layer, primarily apply to the Black Sea. However, these findings may also have a wider application. In particular, the shallower water masses of oxygen-deficient zones (ODZs) are similarly characterized by the formation of a layer of suspended small particles that can be optically detected by bₚ₃ and the attenuation coefficients of particles (Spinrad et al., 1989; Naqvi et al., 1993; Whitmire et al., 2009). This layer is mainly linked to N₂-yielding microbial communities because (1) its location coincides with the maxima of N₂ excess, microbial metabolic activity, and nitrite (NO₂⁻), the intermediate product of denitrification and anammox that is mainly accumulated in the N₂-yielding section: Spinrad et al., 1989; Naqvi et al., 1991, 1993; Devon et al., 2006; Chang et al., 2010, 2012; Ulloa et al., 2012; Wojtasiewicz et al., 2020), and (2) MnO₂ is not accumulated as in the Black Sea (Martin and Knauer, 1984; Johnson et al., 1996; Lewis and Luther, 2000). Therefore, our findings suggest that highly resolved vertical profiles of bₚ₃ and O₂ can potentially be used as a combined proxy to define the effective N₂-production section of ODZs. Such a definition can be key to better-constrained global estimates of N₂ loss rates because it can allow us to (1) accurately predict the oxygen-poor water volume where around 90 % of N₂ is produced in the ODZ core (Babbin et al., 2014) and (2) evaluate how the location and thickness of the N₂-yielding section vary due to changes in the biogeochemical factors that modulate anammox and heterotrophy denitrification.

Global estimates of N₂ production differ by 2–3-fold between studies (e.g., 50–150 Tg N yr⁻¹, Codispoti et al., 2001; Bianchi et al., 2012, 2018; DeVries et al., 2012; Wang et al., 2019). These discrepancies are caused in part by inaccurate estimations of the oxygen-poor volume of the N₂-production section. Other sources of uncertainties arise from the methods applied to estimate the amount of particulate organic matter (POM) that fuels N₂ production. For instance, POM fluxes and their subsequent attenuation rates are not well resolved because they are computed, respectively, from satellite-based primary-production algorithms and generic power-law functions (Bianchi et al., 2012, 2018; DeVries et al., 2012). POM-flux estimates based on these algorithms visibly exclude (1) POM supplied by zooplankton migration (Kiko et al., 2017; Tutasi and Escribano, 2020), (2) substantial events of POM export decoupled from primary production (Karl et al., 2012), and (3) the role of small particles derived from the physical and biological fragmentation of larger ones (Karl et al., 1988; Briggs et al., 2020), which are more efficiently remineralized by bacteria in ODZs (Cavan et al., 2017). In addition, these estimates do not take into con-
consideration the inhibition effect that O$_2$ intrusions may have on N$_2$-yielding rates (Whitmire et al., 2009; Ulloa et al., 2012; Dalsgaard et al., 2014; Peters et al., 2016; Margolskee et al., 2019).

Overall, mechanistic predictions of N$_2$ production misrepresent the strong dynamics of the biogeochemical and physical processes that regulate them. Consequently, it is still debated whether the oceanic nitrogen cycle is in balance or not (Codispoti, 2007; Gruber and Galloway, 2008; DeVries et al., 2012; Jayakumar et al., 2017; Bianchi et al., 2018; Wang et al., 2019). The subsiding uncertainty points to a compelling need for alternative methods that allow accurate refinement of oceanic estimations of N$_2$ production.

Our study supports the proposition that robotic observations of b$_{bp}$ and O$_2$ can be used to better delineate the N$_2$-yielding section at the appropriate spatial (e.g., vertical and regional) and temporal (e.g., event, seasonal, interannual) resolutions. In addition, POM fluxes and N$_2$ can be simultaneously quantified using the same float technology (BGC-Argo, Bishop and Wood, 2009; Dall’Olmo and Mork, 2014; Reed et al., 2018; Boyd et al., 2019; Estapa et al., 2019; Rasse and Dall’Olmo, 2019). These robotic measurements can contribute to refining global estimates of N$_2$ production by better constraining both the oxygen-poor section where N$_2$ is produced and POM fluxes that fuel its loss. Ultimately, O$_2$ intrusions into the N$_2$-yielding section can potentially be quantified by BGC-Argo floats to assess their regulatory effect on N$_2$ production.

**5 Conclusions**

Our results along with those from previous studies suggest that the b$_{bp}$-layer of the oxygen-poor Black Sea is at least partially composed of nitrate-reducing SAR11 and anammox, denitrifying, and sulfur-oxidizing bacteria. The location and thickness of this layer show strong spatial–temporal variability, mainly driven by the ventilation of oxygen-rich subsurface waters and nitrate available to generate N$_2$, respectively. Such variations in the characteristics of the b$_{bp}$-layer highlight that N$_2$-production rates can be highly variable in the Black Sea. We therefore propose that high-resolution measurements of O$_2$ and b$_{bp}$ can potentially be exploited as a combined proxy to delineate the effective N$_2$-yielding section of ODZs. This proposition is in part supported by evidence that the b$_{bp}$-layer and a majority of N$_2$-yielding microbial communities are both confined in the shallower oxygen-poor water masses of ODZs. We however recommend investigation into the key biogeochemical drivers of the b$_{bp}$-layer for each ODZ. This information will be critical for validating the applicability of the b$_{bp}$-layer in assessing spatial–temporal changes in N$_2$ production.

Finally, it is evident that BGC-Argo float observations can acquire essential proxies of N$_2$ production and associated drivers at appropriate spatial and temporal resolutions.

The development of observation–modeling synergies therefore has the potential to deliver an unprecedented view of N$_2$-yielding drivers if robotic observations become an integrated part of model validation. Ultimately, this approach could prove essential for reducing present uncertainties in the oceanic N$_2$ budget.
Appendix A: Sampling locations and time series of floats 7900591 and 6900807

Figure A1. Sampling locations of floats (a) 7900591 and (b) 6900807 between December 2013 and July 2019. Colored squares and hexagons indicate the date (color bar) for a given profile of floats 6900807 and 7900591, respectively.

Figure A2. Time series of (a) $S$, (b) $O_2$, (c) $\log(\text{chl})$, and (d) $\log(b_{bp})$ for float 7900591. The blue line in (c) indicates the mixed layer depth. The red lines in (c) and (d) show the base of the productive region. Isopycnals 15.79 and 16.30 kg m$^{-3}$ describe the top and bottom of the oxygen-poor zone (OP$_{DA}$), respectively. SU, A, W, and SP stand for summer, autumn, winter, and spring, respectively. The colored horizontal line at the bottom indicates the sampling site for a given date (Fig. A1). The horizontal white lines in (d) are the profiles used to (1) delimit the OP$_{DA}$ and (2) find the isopycnals at which $b_{bp}$ is maximum in the OP$_{DA}$. chl is set to zero in the OP$_{DA}$ due to fluorescence contamination (Stanev et al., 2017).
Figure A3. Same as Fig. A2 but for float 6900807.
Data availability. These data were collected and made freely available by the International Argo Program and the national programs that contribute to it (Argo, 2020). The Argo Program is part of the Global Ocean Observing System. Data on N$_2$:Ar ratios are freely available at https://doi.org/10.1029/2018GB006032 (Fuchsm et al., 2019).

Author contributions. RR conceptualized the study, wrote the original draft, and generated all the figures. HC contributed to tuning the study’s conceptualization and figure design. AP processed all BGC-Argo float data. RR and HC reviewed and edited the final manuscript.

Competing interests. The authors declare that they have no conflict of interest.

Acknowledgements. This study was conducted under the framework of the Marie Skłodowska-Curie Individual Fellowship awarded to Rafael Rasse (NOCEANIC project). This study is a contribution to the REMOCEAN project (H. Claustre), and the final writing was funded by the REFINE project (H. Claustre). We finally thank Clara A. Fuchsm and the anonymous reviewer for their accurate and constructive feedback, which allowed us to significantly improve the original version of the manuscript.

Financial support. This research has been supported by the European Union’s Horizon 2020 research and innovation program (NOCEANIC project, grant no. 839062), and the European Research Council, Seventh Framework Programme (REMOCEAN project: grant no. 246777; and REFINE project: grant no. 834177).

Review statement. This paper was edited by Aninda Mazumdar and reviewed by Clara A. Fuchsm and one anonymous referee.
