A review of the role of DNA methylation in stem cell renewal and multipotency

Introduction
Multipotent stem cells extracted from many adult tissues are an attractive stem cell resource for the replacement of damaged tissues in regenerative medicine. The requirements for cellular differentiation of an adult stem cell are a loss of proliferation potential and a gain of cell-type identity. These processes could be restricted by epigenetic modifications that prevent the risks of lineage-unrelated gene expression or the undifferentiated features of stem cells in adult somatic cells. In this review, we focus on the role of DNA methylation in controlling the transcriptional activity of genes important for self-renewal, the dynamism of CpG methylation of tissue-specific genes during several differentiation programs, and whether the multilineage potential of adult stem cells could be imposed early in the original precursor stem cells through CpG methylation. Additionally, we draw attention to the role of DNA methylation in adult stem cell differentiation by reviewing the reports on spontaneous differentiation after treatment with demethylating agents and by considering the evidence provided by reprogramming of somatic cells into undifferentiated cells (that is, somatic nuclear transfer or generation of induced pluripotent cells). It is clear from the evidence that DNA methylation is necessary for controlling stem cell proliferation and differentiation, but their exact contribution in each lineage program is still unclear. As a consequence, in a clinical setting, caution should be exerted before employing adult stem cells or their derivatives in regenerative medicine and appropriate tests should be applied to ensure the integrity of the genome and epigenome.

Abstract
Owing to their potential for differentiation into multiple cell types, multipotent stem cells extracted from many adult tissues are an attractive stem cell resource for the replacement of damaged tissues in regenerative medicine. The requirements for cellular differentiation of an adult stem cell are a loss of proliferation potential and a gain of cell-type identity. These processes could be restricted by epigenetic modifications that prevent the risks of lineage-unrelated gene expression or the undifferentiated features of stem cells in adult somatic cells. In this review, we focus on the role of DNA methylation in controlling the transcriptional activity of genes important for self-renewal, the dynamism of CpG methylation of tissue-specific genes during several differentiation programs, and whether the multilineage potential of adult stem cells could be imposed early in the original precursor stem cells through CpG methylation. Additionally, we draw attention to the role of DNA methylation in adult stem cell differentiation by reviewing the reports on spontaneous differentiation after treatment with demethylating agents and by considering the evidence provided by reprogramming of somatic cells into undifferentiated cells (that is, somatic nuclear transfer or generation of induced pluripotent cells). It is clear from the evidence that DNA methylation is necessary for controlling stem cell proliferation and differentiation, but their exact contribution in each lineage program is still unclear. As a consequence, in a clinical setting, caution should be exerted before employing adult stem cells or their derivatives in regenerative medicine and appropriate tests should be applied to ensure the integrity of the genome and epigenome.
in controlling chromatin conformation since histone modifications and non-coding RNA regulation also collaborate in its control. So, we must consider the existence of an ‘epigenetic code’ in which several epigenetic factors act in a gradual and progressive manner for controlling chromatin structure.

Currently, much attention is being paid to the effects of CpG methylation on stemness and differentiation. The first piece of evidence came from the observation that important genes for the maintenance of ES cells, such as Oct4 and Nanog genes, are usually hypomethylated when activated but became hypermethylated during differentiation [5,6]. Knowledge of the genome-wide contribution of CpG methylation to stem cell maintenance and differentiation has increased in recent years, mainly because of the development of technical approaches for assessing epigenetic factors. High-throughput strategies demonstrate that human ES cells have a unique CpG methylation signature that, in combination with histone modifications, drives stem cell differentiation through the restriction of the developmental potential of progenitor cells [7,8]. In comparison with the broad-ranging information obtained from ES cells, the role of CpG methylation in regulating differentiation of adult stem cells has been less extensively examined. In this review, we consider the reported evidence of how the developmental potential of adult stem cells could be restricted by the gain of DNA methylation of self-renewal genes (preventing the undifferentiated features of stem cells in adult somatic cells) and the DNA methylation-dependent control of tissue-specific genes (abolishing the risks of lineage-unrelated gene expression). The opportunities that this presents for manipulating the epigenome by means of pharmacological treatments and its consequences for stem cell differentiation and reprogramming will be analyzed.
DNA methylation, global chromatin context, and stemness

It is important to point out that the relationship between promoter DNA methylation and promoter activity depends on the CpG content of the promoters: high CpG promoters (HCPs), intermediate CpG promoters, or low CpG promoters (LCPs). In ES cells and multipotent progenitor cells, HCP promoters are characterized by low DNA methylation levels, whereas LCP promoters are enriched in DNA methylation [6,8,9] (Figure 2). Furthermore, specific histone modifications (that is, H3K4me3 and H3K27me3) in HCPs appear to be more decisive for expression of the corresponding genes and suggest a degree of protection from DNA methylation [10] (Figure 2). Conversely, methylated LCP promoters are depleted of bivalent histone marks and are mostly repressed in ES cells [6,8,9] (Figure 2). It is suggested that silencing of pluripotency-related genes occurs by means of CpG promoter hypermethylation, whereas gain of differentiation features is defined by gene regulation of Polycomb targets [8].

Specific epigenetic features at a global level also underpin the pluripotency of ES cells. Recent studies have demonstrated that ES cell chromatin is in a highly dynamic state with global DNA hypomethylation and a general abundance of transcriptionally active chromatin marks such as H3K4me3 and acetylation of histone H4, which is reflected in the relatively decondensed chromatin of ES cells [2,11]. This global lack of DNA methylation in stem cells could be associated with the ability of such cells to activate a wide range of cell-type-specific genes during the differentiation programs [2]. It must not be forgotten that DNA methylation and histone modifications do not work alone and that the epigenetic inactivation of differentiation-specific genes in stem cells (that is, Hox and Pax family of genes) is usually repressed by alternative chromatin remodeling factors, such as Polycomb proteins [11,12]. Consequently, further study of the interplay of all of the chromatin regulators is essential for understanding the dynamism of transcriptional control during stem cell renewal and differentiation.

DNA methylation-dependent regulation of genes associated with self-renewal of stem cells

It has been widely reported that maintenance of the pluripotency state is conferred by a set of development-associated transcription factors – such as OCT4, NANOG, and SOX2 – that occupy promoters of active genes associated with self-renewal [13,14]. Expression of the aforementioned transcription regulators is usually controlled by CpG promoter methylation, and differentiation of ES cells is accomplished by partial or full methylation of pluripotency-associated genes, resulting in their downregulation [6,15-17]. The opposite association has been found in the reprogramming of induced pluripotent stem (iPS) cells from differentiated cells, in which unmethylated active promoters of ES cell-specific genes were described [18] (Figure 2). Despite the considerable information about silencing of pluripotency ES genes during differentiation, very little is known about the epigenetic control of genes associated with self-renewal and maintenance of multipotent adult stem cells. In adipose-derived stem cells (ASCs) and mesenchymal stem cells from bone marrow (BM-MSCs), OCT4 is silenced by promoter hypermethylation, whereas Nanog and Sox2 are unmethylated despite the repressed state of the genes [19]. The same patterns of methylation were found in differentiated fibroblasts and keratinocytes [19]. It seems that, whereas Oct4 regulation is strongly influenced by CpG promoter hypermethylation, the control of Nanog and Sox2 expression could be due to other repressive mechanisms such as histone modification patterns [19]. Enrichment of H3K27me3 and H3K9me3 and reduction of H3K79me3 have been described in the Nanog and Sox2 promoters of ASCs and differentiated cells but not in pluripotent cells [20]. These results demonstrate that the transcriptional repression mechanisms could vary depending on the gene and the state of cellular differentiation (that is, multipotency versus differentiation) [19] and could constitute a mechanism for preventing aberrant reactivation of pluripotency and minimizing the risk of de-differentiation [21]. In line with this hypothesis, ES cells with genetic mutations of DNA methyltransferase result in rapid apoptosis-mediated cell death [22,23].

The promoter methylation status of additional stem cell-determining genes for self-renewal (not exclusively markers of pluripotency) has also been investigated [24]. Silencing of the mesodermal transcription factor Brachyury gene during differentiation from BM-MSCs to mesodermal lineages involves hypermethylation of its promoter but not changes in promoter hypermethylation of genes such as LIN28, NESTIN, or ZFP42. This could be associated with changes of expression during differentiation of BM-MSCs [24]. Currently, we have a limited understanding of how multipotency is established and maintained in adult stem cells, and it would be very interesting to study the CpG promoter methylation status of transcription factors that confer multipotency on adult stem cells beyond the traditional role of pluripotency genes such as Oct4, Nanog, and Sox2.

Specific CpG methylation during differentiation of multipotent stem cells

Cellular differentiation is determined by a loss of proliferation potential and a gain of cell-type identity. This reduction of developmental potential could be
Figure 2. Chromatin states during differentiation of adult stem cells and reprogramming of somatic cells. The figure shows the epigenetic alterations of genes associated with pluripotency, cell maintenance, and lineage specification during stem cell differentiation. CpG methylation is grouped into three types of promoters classified with respect to their CpG content: high CpG promoter (HCP), intermediate CpG promoter (ICP), and low CpG promoter (LCP). Bivalent domains of histone marks (trimethylated histone H3 at lysine 4 and trimethylated histone H3 at lysine 27) are represented. Reprogramming of somatic cells toward pluripotent cells – that is, induced pluripotent cells (iPS) – implies a turnover of the epigenetic landscape of adult differentiated cells, including silencing of tissue-specific genes and activation of pluripotency-related genes.
restricted by epigenetic modifications that prevent the risks of lineage-unrelated gene expression or undifferentiated features of stem cells in adult cells [3]. However, the role of specific promoter methylation in controlling gene differentiation remains a matter of controversy. On one hand, there are some clues in favor of the hypothesis that cell type-specific patterns of DNA methylation influence cell type-specific gene expression and, by extension, cellular differentiation. For example, promoter methylation of SERPINB5 is inversely correlated with the unique expression of SERPINB5 in epithelial cells [25], and the rSPHK1 and hSLC6A8 promoter hypermethylation associated with gene silencing in specific tissues allows expression in unmethylated brain tissue only [26,27]. On the other hand, genome-wide analysis of CpG methylation changes during the conversion of human pluripotent/multipotent stem cells into differentiated somatic cells reveals small changes in DNA methylation at promoter regions [8,9,28-30]. For example, lineage commitment of neural progenitor cells into terminally differentiated neurons occurs with a very moderate number of promoter DNA hypermethylated genes as cells differentiate [8]. Further work is needed to test whether these weak associations between gene repression and CpG hypermethylation during differentiation are due to limitations of the analytical techniques or to the existence of additional methylation-independent regulatory mechanisms.

**Does CpG methylation of multipotent stem cells restrict lineage specification?**

One of the main features of adult stem cells is their multipotency (that is, their ability to differentiate into a number of cell types), but, in contrast to pluripotent cells, they are restricted to those of a closely related family of cells. For example, BM-MSCs primarily form mesodermal-specific cell types such as chondrocytes, myocytes, adipocytes, or osteoblasts [1]. However, we should remember that, given the information collected in recent years, this could be a very general statement, and there is some evidence to suggest that lineage restriction could be more permissive. For instance, BM-MSCs could be differentiated into cells of all three germ layers and generate tissues such as osteocytes (mesoderm), hepatocytes (endoderm), or neurons (ectoderm) [31-33]. Multipotent cells isolated from different tissues have common in vitro phenotypic and functional characteristics (for example, MSCs share fibroblast-like morphology, plastic adherence, proliferation ability, and clonogenicity) but differ in the expression of specific lineage markers (for example, ASCs and BM-MSCs differ in the expression of the surface markers CD90, CD105, CD106, and adhesion molecules [34,35] and in their differentiation potential). Since gene expression in adult stem cells is regulated by epigenetic processes, a question arises: is the differentiation potential in adult stem cells predicted by DNA methylation of specific lineage promoters? There is some evidence in favor of a differentiation restriction imposed by promoter hypermethylation in progenitor stem cell states, whereas promoter hypomethylation does not have any predictive value with respect to differentiation potential [35,36]. Characterization of DNA methylation profiles of all human RefSeq promoters in mesenchymal adult stem cells from various origins, including adipose, hematopoietic, and neural progenitors and muscle tissue, shows that the majority of the lineage-specific genes are hypomethylated even if the progenitor is not able to differentiate into this specific lineage [10]. There are some examples of epigenetic silencing associated with restriction to differentiation: endothelial markers such as CD31 and CD144 are strongly methylated in ASCs that show very limited capacity for endothelial differentiation [36] or osteogenic and adipogenic restriction of C2C12 myoblast cell line differentiation [37]. Furthermore, the restriction for differentiation in specific programs imposed by means of DNA methylation is established early in development, in the progenitor state, and persists after differentiation, as most of the hypermethylated promoters in undifferentiated cells remain hypermethylated in somatic cells [10,37]. This is in agreement with the low level of de novo methylation described after differentiation of adult stem cells [8,9]. Results lead to the conclusion that the differentiation restriction associated with promoter hypermethylation clearly differs between pluripotent and multipotent cells: lineage-specific promoters are mostly hypermethylated in ES cells [6] in contrast to the low-percentage hypermethylation found in MSCs [35].

**Treatment with demethylating agents results in spontaneous differentiation**

The involvement of DNA methylation in controlling the differentiation potential of stem cells has been supported by several reports of spontaneous differentiation after treatment with demethylating agents (Table 1). For example, the use of 5-aza-2’-deoxycytidine (5-ADC) promotes differentiation of ASCs into cardiac myogenic cells [38]. Pretreatment with 5-ADC also drives the osteogenic differentiation of BM-MSCs by enhancing the expression of osteogenic genes (such as Dlx5) associated with demethylation of its CpG shore [39,40]. However, we must remember that DNA methylation is just one component of the epigenetic machinery and that removing DNA methylation is often insufficient to reactivate gene expression (Table 1). Treatments with the histone deacetylase (HDAC) inhibitor trichostatin A (TSA) enhance chondrogenic differentiation of BM-MSCs accomplished by increased expression of Sox9 [41]. Similarly, neural
induction was achieved when multipotent stem cells were exposed to TSA simultaneously with 5-ADC [42]. Furthermore, the effects of treatments with HDAC inhibitors are known to alter DNA methylation levels [41,42]. Additional evidence for the role of epigenetic control in differentiation comes from the functional consequences of defects in enzymes of the epigenetic machinery. For example, recovery of the expression of a defect in a histone modifier (NSD1) suppresses cell growth and increases the differentiation of neuroblastoma cell lines [43]. Recovery of epigenetic patterns, by treatment with epigenetic drugs or by genetic models, highlights the potential of epigenetic modifiers, possibly in combination with other factors, to enhance the ability of multipotent stem cells to form functional differentiated cells and has significant therapeutic implications. Some consistent lines of evidence support this therapeutic application since epigenetic drugs, among them demethylating agents, have shown significant antitumor activity and the US Food and Drug Administration has approved the use of some of them to treat patients with cancer [4]. Indeed, new HDAC inhibitors (that is, romidepsin, belinostat, or givinostat) that are currently being tested in clinical trials for antitumor activity and the US Food and Drug Administration has approved the use of some of them to treat patients with cancer [4]. Indeed, new HDAC inhibitors (that is, romidepsin, belinostat, or givinostat) that are currently being tested in clinical trials for antitumor activity and [64,65], suggesting that global epigenetic modifications, though necessary, are not sufficient to transdifferentiate by themselves [46]. These findings underline the necessity of evaluating in more detail the importance of epigenetic chromatin remodeling for establishing and maintaining stemness or, on the other hand, initiating a differentiation program. The reprogramming of somatic cells provides a new opportunity to study the contribution of epigenetics to differentiation. A mature cell can be converted into a pluripotent state by three experimental approaches: somatic nuclear transfer into enucleated oocytes, the in vitro application of a defined set of transcription factors creating iPS cells, or fusing ES cells with somatic cells to generate heterokaryons and hybrids [47]. Epigenetic rearrangements are observed independently of the technique [48,49]. In fact,
there is evidence that HDAC inhibitors and DNA demethylating agents are useful for enhancing iPSC reprogramming [50,51]. A prerequisite in reprogramming of iPSC from somatic cells is that some stemness-related promoters become demethylated. How might this demethylation be achieved? It could be done through a DNA repair mechanism [52,53] or by the recent discovery of TET proteins, a group of enzymes that convert methylated 5-methylcytosine to 5-hydroxymethylcytosine [54]. Although experimental models for reprogramming have generated a considerable amount of information, many questions remain. How different is the epigenetic regulation of pluripotent and multipotent cells? Does CpG methylation underpin self-renewal in adult stem cells, as it does in ES cells? Do epigenetic marks define the lineage potential of an adult stem cell? Is it possible to revert the differentiation program by manipulating the epigenome? How safe is this reversion? The recent discovery that nearly one quarter of all methylation identified in ES cells was found in a non-CG context [55] suggests that the genomic context must also be addressed. Do ES cells use a different methylation mechanism for gene regulation? Furthermore, long-term in vitro culture of adult stem cells, a prerequisite for large-scale expansion previous to implantation with therapeutic purposes, showed specific alterations of CpG island methylation [56]. As a consequence, it is necessary to optimize and standardize the experimental protocols used for in vitro expansion which minimize epigenetic-related instability. In conclusion, although manipulation of epigenetic activity might be an interesting means of generating populations of specific cell types, additional epigenetic research on the understanding of stem cell biology must be done before they can be used as differentiation agents in stem cell-based therapies.
