Abstract

Two photon collisions at high energy have an important theoretical advantage: the simplicity of the initial state, which gives us a unique opportunity to calculate these processes for large virtualities of both photons in perturbative QCD approach. In this paper we study QCD saturation in two photon collisions in the framework of the Glauber-Mueller approach. The Glauber-Mueller formula is derived emphasizing the impact parameter dependence ($b_t$) of the dipole-dipole amplitude. It is shown that non-perturbative QCD contributions are needed to describe large $b_t$-behaviour, and the way how to deal with them is suggested. Our approach can be viewed as the model for the saturation in which the entire impact parameter dependence is determined by the initial conditions. The unitarity bound for the total cross section, its energy dependence as well as predictions for future experiments are discussed.

It is argued that the total cross section increases faster than any power of $\ln(1/x)$ in a wide range of energy or $x$, namely \[ \sigma(\gamma^*-\gamma^*) \sim (1/Q^2) \exp(a\sqrt{\ln(1/x)}) \leq 1/m_{\pi}^2 \] where $\exp(a\sqrt{\ln(1/x)})$ reflects the $x$ dependence of the gluon density $xG \sim \exp(2a\sqrt{\ln(1/x)})$ and $m_{\pi}$ is the pion mass.

1 Introduction.

Two photon collisions at high energy have three theoretical advantages over hadronic collisions or/and deep inelastic scattering:

- The simplicity of the initial state, which allows processes, such as large transverse momentum hadronic jet production, to be calculated exactly to lowest order in perturbative theory. With the advent of high quality experimental data, theoretical analysis also focus on higher order corrections to the basic processes which can provide an interesting test of the theory \([1]\);

- Scattering of two photons with large but equal virtualities gives unique access to BFKL emission \([2]\), making this process very useful for studying the dynamics \([3, 4, 5, 6, 7, 8, 9]\);

- Scattering of two virtual photons with large virtualities allows one to study shadowing (screening) corrections on the solid theoretical basis of perturbative QCD \([10]\).

It is well known that the correct degrees of freedom at high energy are not quarks or gluon but colour dipoles \([11, 12, 13, 14]\) which have transverse sizes \(r_t\) and the fraction of energy \(x\). Therefore, two photon interactions occur in two successive steps. First, each of virtual photon decays into a colour dipole (quark - antiquark pair) with size \(r_t\). At large value of virtualities the probability of such a decay can be calculated in pQCD. The second stage is the interaction of colour dipoles with each other. The simple formula (see for example Ref. \([15]\)) that describes the process of interaction of two photons with virtualities \(Q_1\) and \(Q_2\) is (see Fig. 1)

\[
\sigma(Q_1, Q_2, W) = \int d^2b_t \sum_{a,b}^{N_f} \sigma_{dd}^{ab}(\tilde{x}_{ab}, r_{1,t}, r_{2,t}; b_t)
\]

where the indices \(a\) and \(b\) specify the flavours of interacting quarks, \(T\) and \(L\) indicate the polarization of the interacting photons. The \(r_i\) denote the transverse separation between quark and antiquark in the dipole (dipole size) and \(z_i\) are the energy fractions of the quark in the photon \(i\). \(\sigma_{ab}^{dd} = 2N((\tilde{x}_{ab}, r_{1,t}, r_{2,t}; b_t)\) where \(N\) is the imaginary part of the dipole - dipole amplitude at energy \(x\) given by

\[
\tilde{x}_{ab} = \frac{Q_1^2 + Q_2^2 + 4m_a^2 + 4m_b^2}{W^2 + Q_1^2 + Q_2^2}
\]

where \(m_a\) is the mass of the quark with flavour \(a\). \(b_t\) is the impact parameter for dipole-dipole interaction and it is equal the transverse distance between the dipole centers of mass. It is clear that \(\sigma_{ab}^{dd}\) has a meaning of \(d\sigma/d^2b_t\).

The wave functions for virtual photon is known \([16]\) and they are given by
\[ \Psi_a^e(Q; z, r_t) |^2 = \frac{6\alpha_{em}}{\pi^2} Z_a^2 \left( (z^2 + (1-z)^2) \hat{Q}_a^2 K_1^2(Q_a r_t) + m_a^2 K_0^2(Q_a r_t) \right) \] (1.3) 

\[ \Psi_L^a(Q; z, r_t) |^2 = \frac{6\alpha_{em}}{\pi^2} Z_a^2 Q^2 z^2 (1-z)^2 K_0^2(\hat{Q}_a r_t) \] (1.4)

with \( \hat{Q}_a^2 = z(1-z)Q^2 + m_a^2 \) where \( Z_a \) and \( m_a \) denote the faction of charge and mass of the quark of flavour \( a \).

The main contribution in Eq. (1.1) is concentrated at \( r_{1,t} \approx 1/Q_1 \ll 1/\mu \) and \( r_{1,t} \approx 1/Q_2 \ll 1/\mu \) where \( \mu \) is the soft mass scale. Therefore, at first sight, we can safely use pQCD for calculation of the dipole-dipole cross section \( \sigma \) in Eq. (1.1). The objective of this paper is to investigate the dipole-dipole cross section at high energy (low \( x \)) where QCD saturation is expected \[17, 18, 19\]. The first analysis based on Golec-Biernat and Wüsthoff model \[20\] has been performed in Ref. [10]. Here we will extend this analysis by using the Glauber - Mueller approach \[11, 12, 13\] with special focus on the impact parameter dependence which was completely omitted in the GBW model as well as in Ref. [10].

In the next section we discuss the dipole-dipole interaction in the Born approximation of pQCD. We show that this approximation leads to \( \sigma \) which decreases as a power of \( b_t \). It turns out that \( \sigma \rightarrow 1/b_t^4 \) for large \( b_t > r_{1,t} \) and \( r_{2,t} \). Of course, such a behaviour will not change its character in higher orders of pQCD (see Refs \[21, 22, 23, 24\]) since it is a direct consequence of the massless gluon in QCD. Using the Born approximation as the example we consider the non-perturbative contribution that provides an exponential decrease at large values of \( b_t \gg 1/m_\pi \).

Section 3 is devoted to Glauber - Mueller formula in the case of the DGLAP emission \[25\]. Here, we use the advantage of photon - photon scattering with large photon virtualities, since we can calculate the gluon density without uncertainties related to non-perturbative initial distributions in hadronic target. It is well known that no \( b_t \) dependence is induced by DGLAP emission at least for large values of the impact parameter. Therefore, the entire impact parameter dependence is due to the Born Approximation cross section. In other words, we can use our approach as an explicit illustration of the point of view that the non-perturbative large \( b_t \geq 1/2m_\pi \), where \( m_\pi \) is the pion mass, is determined by the initial condition (see Refs.
2 Dipole-dipole interaction in the Born approximation.

The Born approximation for the dipole-dipole scattering amplitude is shown in Fig. 2. To obtain the expression for $\sigma_{dd}(\vec{x}, r_{1,t}, r_{2,t}; b_t)$ (see Fig. 1) we need to calculate the diagrams in the momentum representation and then to rewrite them in space-time representations. The conjugated variables to $p_t$ and $l_t$ will be the size of the dipole (say $r_{1,t}$ and the impact parameter $b_t$. The detailed calculation performed in light-cone technique (see for example Ref. [26]) has been performed in [27]. The answer is

$$\sigma(\vec{x}, r_{1,t}, r_{2,t}; b_t) = \pi \alpha_s^2 \frac{N_c^2 - 1}{2 N_c^2} \left( \ln \left( \frac{\vec{b} - \vec{z}_1 r_{1,t} - \vec{z}_2 r_{2,t}}{\vec{b} - \vec{z}_1 r_{1,t} - \vec{z}_2 r_{2,t}} \right) \right)^2$$

(2.5)

where $z_i$ is the fraction of the energy of the dipole carried by quarks and $\bar{z}_i = z_i - 1$. All vectors are two dimensional in Eq. (2.5).
Eq. (2.5) has a simpler form if we assume that $z_i = 1/2$. Namely,

$$
\sigma(\bar{x}, r_{1,t}, r_{2,t}; b_t) = \pi \alpha_s^2 \frac{N_c^2 - 1}{2 N_c^2} \left( \ln \left( \frac{\bar{b} + \bar{R}}{\bar{b} + \bar{\Sigma}} \right) \frac{(\bar{b} - \bar{R})^2}{(\bar{b} - \bar{\Sigma})^2} \right)
$$

(2.6)

where $\bar{R} = \frac{\bar{r}_{1,t} - \bar{r}_{2,t}}{2}$ and $\bar{\Sigma} = \frac{\bar{r}_{1,t} + \bar{r}_{2,t}}{2}$. We note that we do not find the dipole-dipole cross section in impact parameter representation in Ref. [27], but the calculation is so simple that we just present the answer.

To simplify our further calculations we restrict ourselves by DGLAP emission assuming that $r_{1,t}$ is much smaller than $r_{2,t}$. It is instructive to find two different limits in Eq. (2.5).

- $b_t \gg r_{2,t} \gg r_{1,t}$. Expanding Eq. (2.5) one can obtain after integration over azimuthal angle

$$
\sigma(\bar{x}, r_{1,t}, r_{2,t}; b_t) \rightarrow \pi \alpha_s^2 \frac{N_c^2 - 1}{2 N_c^2} \frac{r_{1,t} r_{2,t}^2}{b_t^4}.
$$

(2.7)

- $b_t \ll r_{1,t} \ll r_{2,t}$.

$$
\sigma(\bar{x}, r_{1,t}, r_{2,t}; b_t) \rightarrow \pi \alpha_s^2 \frac{N_c^2 - 1}{2 N_c^2} \frac{r_{1,t} r_{2,t}^2}{z_2^2 z_2^2 r_{2,t}^2}.
$$

(2.8)

Therefore, we can suggest a simple formula which covers two these limits, namely

$$
\sigma(\bar{x}, r_{1,t}, r_{2,t}; b_t) = \pi \alpha_s^2 \frac{N_c^2 - 1}{2 N_c^2} \frac{r_{1,t} r_{2,t}^2}{b_t^2 + z_2^2 z_2^2 r_{2,t}^2}.
$$

(2.9)

For further estimates we will use Eq. (2.9) which reflects all qualitative features of the full expression of Eq. (2.5) but considerably simplifies the calculations.

Eq. (2.5) as well as Eq. (2.9) leads to power-like decrease at large values of $b_t$, namely, $\sigma(\bar{x}, r_{1,t}, r_{2,t}; b_t) \propto \frac{1}{b_t^4}$. Such behaviour cannot be correct since it contradicts to the general consequence of analyticity and crossing symmetry of the scattering amplitude. Since the spectrum of hadrons has no particles with mass zero, the scattering amplitude should decrease as $e^{-2m_{\pi} b_t}$ [28]. Certainly we need to take into account non-perturbative corrections to heal this problem as has been noticed in many papers [29, 21, 22, 23, 24, 30]. We suggest the procedure how to introduce such corrections which is based on the hadron-parton duality in the spirit of the QCD sum rules [31]. This procedure consists of two steps: (i) first, we rewrite Eq. (2.9) in the momentum transfer representation ($t = -q_t^2$) in the form of a dispersion relation with respect to the mass of two gluons in $t$-channel; (ii) secondly, we claim that this dispersion integral gives correct contribution of all hadronic states on average. Therefore, the model for the non-perturbative contribution is the integral over a two gluon state in the $t$-channel but with the restriction that two gluon mass should be larger than the minimum mass in hadronic states, namely, larger than $2m_{\pi}$. As in QCD sum rules [31] we assume that the integrand at
large mass of two gluon state can be found in perturbative QCD, while for small mass we have to include the realistic (experimental) spectrum of hadrons. The integration from \(2m_s\) means that we believe that we can approximate the dispersion integral even in region of small masses by the perturbative QCD contribution. This procedure corresponds to the approximation that has been used in Ref. [30]. We can also evaluate this integral differently: to take into account the first resonance (glueball) explicitly and to use pQCD approach to estimate the dispersion integral for masses larger than \(s_0\), the value for \(s_0\) can be taken from a QCD sum rules calculation of the glueball spectrum [31]. Such an approach is closely related to one developed in Ref. [29] and it appears reasonable in pure gluodynamics where we do not have any pions.

Rewriting Eq. (2.9) in the form

\[
\sigma(\vec{x}, r_{1,t}, r_{2,t}; b_t) = \frac{C(r_{1,t}, r_{2,t})}{(b_t^2 + a^2)^2},
\]  

(2.10)

with obvious notation, we can see that

\[
\sigma(\vec{x}, r_{1,t}, r_{2,t}; q^2) = C(r_{1,t}, r_{2,t}) \int b_t db_t \frac{J_0(b q)}{(b_t^2 + a^2)^2} = C(r_{1,t}, r_{2,t}) \frac{q}{2a} K_1(a q)
\]

(2.11)

where \(J_0\) and \(K_1\) are Bessel and McDonald functions respectively. However, we can rewrite \(K_1(a q)\) in a different way as

\[
q K_1(a q) = \int \frac{J_1(\kappa a) \kappa^2 d\kappa}{\kappa^2 + q^2}.
\]

(2.12)

The last integral (see Eq. (2.12)) gives as the dispersion relation, namely,

\[
\sigma(\vec{x}, r_{1,t}, r_{2,t}; t = -q^2) \approx C(r_{1,t}, r_{2,t}) \frac{1}{2a} \int_0^\infty \frac{J_1(\kappa a) \kappa^2 d\kappa}{\kappa^2 - t}
\]

(2.13)

Eq. (2.13) we replace by

\[
\sigma(\vec{x}, r_{1,t}, r_{2,t}; t = -q^2) \approx C(r_{1,t}, r_{2,t}) \frac{1}{2a} \int_0^{\infty} \frac{J_1(\kappa a) \kappa^2 d\kappa}{\kappa^2 - t}
\]

(2.14)

accordingly to our main idea. Returning to the impact parameter representation we obtain

\[
\sigma(\vec{x}, r_{1,t}, r_{2,t}; b_t) = C(r_{1,t}, r_{2,t}) \frac{1}{2a} \int_0^{\infty} \frac{\kappa^2 d\kappa}{\kappa^2 + q^2} \int_0^{\infty} q dq \frac{J_1(\kappa a) J_0(q b_t)}{\kappa^2 + q^2}
\]

\[
= \frac{\pi\alpha_s^2 N_c^2}{2} r_{1,t}^2 r_{2,t}^2 \frac{1}{\sqrt{z_2 z_2}} \int_0^{\infty} \kappa^2 d\kappa J_1(\kappa a) K_0(\kappa b_t)
\]

(2.15)

One can see that \(\sigma \propto e^{-2m_s b_t}\) for \(b_t \gg 1/2m_s\) due to the asymptotic behaviour of the McDonald function \(K_1(\kappa b_t) \rightarrow e^{-2m_s b_t}\) at large \(b_t\).

Therefore, the \(b_t\) behaviour is: for \(1/(2m_s) > b_t > r_{1,t}\) or/and \(r_{2,t}\) the dipole-dipole scattering amplitude falls as \(1/b_t^4\), but for large \(b_t\) (\(b_t > 1/(2m_s)\)) we have normal exponential
decrease as $e^{-2m_{\pi}b_t}$ which has a non-perturbative origin. Eq. (2.15) gives us a rather general way to take into account the non-perturbative contribution, since in this equation we explicitly introduce the minimum mass in the experimental hadronic spectrum. However, as we have mentioned above, we can expect a large mass for the low limit of integration in the dispersion relation of Eq. (2.14) and Eq. (2.15) ($\tilde{Q}_0 > m_{\pi}$) which will lead to $\sigma(\tilde{x}, r_{1t}, r_{2t}; b_t)$ behaviour $\propto e^{-\tilde{Q}_0 b_t}$.

3 Glauber - Mueller formula.

Glauber - Mueller approach takes into account the interaction of many parton showers with the target as it is shown in Fig. 3. Actually this formula was suggested in Refs. [13, 12] but Mueller [11] was the first who proved this formula especially for gluon parton density. The main idea of this approach is that colour dipole is the correct degree of freedom for high energy scattering. Indeed, the change of the value of the dipole size $r_t \, (\Delta r_t)$ during the passage of the colour dipole through the target is proportional to the number of rescatterings (or the size of the target $R$) multiplied by the angle $k_t/E$ where $E$ is the energy of the dipole and $k_t$ is the transverse momentum of the $t$-channel gluon which is emitted by the fast dipole.

$$\Delta r_t \propto R \frac{k_t}{E}. \quad (3.16)$$

Since $k_t$ and $r_t$ are conjugate variables and due to the uncertainty principle

$$k_t \propto \frac{1}{r_t}.$$ 

Therefore,

$$\Delta r_t \propto R \frac{k_t}{E} \ll r_t \text{ if } R \ll r_t^2 E \text{ or } x \ll \frac{1}{2m R}. \quad (3.17)$$

---

‡ This idea was formulated by A.H. Mueller in Ref. [14] a bit later.
3.1 DGLAP emission

We first discuss the generalization of the Born approximation to include the DGLAP emission (see Fig. 3). This will give us the correct description of the one parton shower interaction. The DGLAP equation looks very simple in the region of low \( x \), namely,

\[
\frac{\partial^2 xG(x, r_{1,t}^2, r_{2,t}^2)}{\partial \ln(1/x) \partial \ln(1/r_{1,t}^2)} = \frac{N_c}{\pi} \alpha_S(r_{1,t}) \ xG(x, r_{1,t}^2, r_{2,t}^2), \tag{3.18}
\]

where we consider \( r_{1,t} \ll r_{2,t} \) and rewrite the DGLAP equation in coordinate space. We would like to recall that the DGLAP evolution equation sums the \( (\alpha_S \log Q^2)^n \) contribution, and therefore, we can safely rewrite it in the coordinate representation since within logarithmic accuracy \( \ln Q^2 = \ln(1/r_2^2) \). The initial condition for Eq. (3.18) is \( xG(x, x_0, r_{1,t}^2, r_{2,t}^2) = 1 \). It means that the dipole-dipole cross section at fixed \( b_t \) for one parton shower interaction has a form

\[
\sigma_{\text{dipole}}(x, r_{1,t}, r_{2,t}; b_t) = \sigma_{\text{dipole}}^{BA}(x, r_{1,t}, r_{2,t}; b_t) \ xG(x, r_{1,t}^2, r_{2,t}^2), \tag{3.19}
\]

where \( \sigma_{\text{dipole}}^{BA} \) is the Born approximation for the dipole cross section.

The obvious solution

\[
xG(x, r_{1,t}^2, r_{2,t}^2) = I_0 \left( 2 \sqrt{\xi(r_{1,t}, r_{2,t}) \ln(1/x)} \right) \tag{3.20}
\]

where

\[
\xi(r_{1,t}, r_{2,t}) = \frac{12 N_c}{11 N_c - 2 N_f} \ \frac{\ln(4/(r_{1,t}^2 \Lambda^2))}{\ln(4/(r_{2,t}^2 \Lambda^2))}.
\]

Here, in the arguments of the running QCD coupling we have made the simple replacement \( Q^2 \to 4/r_t^2 \). Within log accuracy we cannot guarantee the coefficient 4 in this expression but as was argued in Ref. [34] this is a reasonable choice (approximation).

Eq. (3.20) has the following asymptotic behaviour

\[
xG(x, r_{1,t}^2, r_{2,t}^2) \to e^{2 \sqrt{\xi(r_{1,t}, r_{2,t}) \ln(1/x)}} \tag{3.21}
\]

which means that \( xG \) grows faster than any power of \( \ln(1/x) \).

Strictly speaking Eq. (3.18) is proven in so called double log approximation of perturbative QCD, in which we consider

\[
\alpha_S \ln(1/x) \ln(Q_1^2/Q_2^2) \approx 1; \\
\alpha_S \ln(1/x) \lesssim 1; \\
\alpha_S \ln(Q_1^2/Q_2^2) \lesssim 1; \\
\alpha_S \ll 1. \tag{3.22}
\]

However, we will use this equation in a wider kinematic region where \( \alpha_S \ln(1/x) \ln(Q_1^2/Q_2^2) < 1 \) and \( \alpha_S \ln(1/x) > 1 \) while \( \alpha_S \ln(Q_1^2/Q_2^2) \approx 1 \). In this kinematic region we should use the
BFKL equation [2]. We view Eq. (3.18) as the limit of the BFKL equation in which we take into account the logarithmic contribution in transverse momentum integration in the BFKL kernel. The justification for such an approach is the fact that the anomalous dimension of the DGLAP equation can be parameterized in simple way [32]

\[ \gamma(\omega) = \alpha_S \left( \frac{1}{\omega} - 1 \right) \]  

(3.23)

The first term in Eq. (3.23) leads to Eq. (3.18) in the region of low \( x \).

Eq. (3.19) and Eq. (3.20) solve the problem of one parton shower interaction in the DGLAP evolution. It should be stressed that the impact parameter dependence enters only in the Born term in Eq. (3.19). The explanation of this fact is very simple if we recall that the logarithmic contribution originates from the integration over transverse momenta large \( q^2/4 \) where \( q^2 \) is the momentum transfered along the DGLAP ladder. Therefore, we have two choices: (i) \( t > Q_2^2 \) and in this case all logs can be summed in a function with the argument \( \ln(Q_1^2/q^2) \), (ii) \( t < Q_2^2 \) and in this case we have function of \( \ln(Q_1^2/Q_2^2) \) as in Eq. (3.20). In our problem we are certainly dealing with the second case since we are mostly interested in large \( b_t \)- behaviour of the scattering amplitude which corresponds to low \( q^2 \) behaviour.

### 3.2 Many parton showers interactions

Since the colour dipoles are correct degrees of freedom the unitarity constraints are for dipole-dipole elastic amplitude \( a_{el}(x, r_1, t, r_2, t; b_t) \) are diagonal and they have the form

\[ 2 \text{Im}a_{el}(x, r_1, t, r_2, t; b_t) \equiv \sigma(x, r_1, t, r_2, t; b_t) = |a_{el}(x, r_1, t, r_2, t; b_t)|^2 + G_{in}(x, r_1, t, r_2, t; b_t) \]

(3.24)

where \( G_{in} \) stands for contribution of all inelastic processes. Eq. (3.24) is exact for dipole-dipole scattering while it has only limited accuracy, for example, for dipole-proton scattering (see Ref. [11]). An experimental manifestation of the poor accuracy of Eq. (3.24) for deep inelastic scattering is the large cross section of so called inelastic diffraction dissociation of proton in an excited state.

Assuming that at high energies the amplitude is pure imaginary, one can find a simple solution to Eq. (3.24), namely,

\[ a_{el}(x, r_1, t, r_2, t; b_t) = i \left( 1 - e^{-\Omega(x, r_1, t, r_2, t; b_t)} \right) ; \]

(3.25)

\[ G_{in}(x, r_1, t, r_2, t; b_t) = \left( 1 - e^{-\Omega(x, r_1, t, r_2, t; b_t)} \right) ; \]

(3.26)

where \( \Omega \) is the arbitrary real function.

In Glauber - Mueller approach the opacity \( \Omega \) is chosen as

\[ \Omega(x, r_1, t, r_2, t; b_t) = \sigma_{dipole}^{OPS}(x, r_1, t, r_2, t; b_t) = \sigma_{dipole}^{BA}(x, r_1, t, r_2, t; b_t) xG(x, r_1^2, r_2^1) , \]

(3.27)
where $\sigma^{\text{ops}}_{\text{dipole}}$ is dipole-dipole cross section in the one parton shower approximation (see Fig. 3).

One can guess that the physical interpretation of Glauber-Mueller formula is simple, namely, it takes into account many parton shower interactions in dipole-dipole scattering, but it does not include a possibility for produced partons from different parton showers to interact. These interactions lead to a more complicated non-linear evolution equation (see Refs. [17, 18, 19, 38]). The influence of non-linear evolution on the photon-photon scattering will be discussed in a separate publication; here we restrict ourselves to consider only the first step of this non-linear evolution which is the Glauber-Mueller approach.

4 Unitarity bound

Using the Glauber - Mueller formula of Eq. (3.25) we can give the unitarity bound for dipole-dipole scattering as well as for $\gamma^* - \gamma^*$ total cross section (see Eq. (1.1)). We consider the Glauber - Mueller formula for the total dipole-dipole cross section, namely,

$$
\sigma_{\text{tot}}^{\text{dd}} = 2 \int d^2 b_t \left(1 - e^{-\Omega(x, r_{1,t}, r_{2,t}; b_1)} \right), \quad (4.28)
$$

with opacity $\Omega$ is given in Eq. (3.27).

The main idea [28] is to replace the full integration over impact parameter in the expression for the total cross section, by integration in two different regions: (i) the first region is $0 \leq b_t \leq b_0(x)$; and (ii) the second one $b_0 \leq b_t \leq \infty$. In the first region we consider $\Omega/2 > 1$ and replace $\text{Im} a_1$ by 1. On the other hand, in the second region we assume that $\Omega/2 < 1$ and expand Eq. (3.25) with respect to $\Omega$ restricting ourselves to the first term of this expansion.

Therefore,

$$
\sigma_{\text{tot}}^{\text{dd}} < 2\pi \left( \int_0^{b_0(x)} db_t^2 1 + \int_{b_0(x)}^\infty db_t^2 \frac{\Omega}{2} \right). \quad (4.29)
$$

$$
\Box \quad b_0 \ll \frac{1}{2 m_\pi}
$$

Let us assume that $b_0 \ll 1/2 m_\pi$. In this case we can use Eq. (2.9) (or Eq. (2.10)) for the $b_t$ - dependence for both intervals. Taking the integral of Eq. (4.29) we have

$$
\sigma_{\text{tot}}^{\text{dd}} < 2\pi \left( b_0^2(x) + \frac{C(r_{1,t}, r_{2,t}) x G(x, r_{1,t}^2, r_{2,t}^2)}{2 (b_0^2(x) + a^2)} \right). \quad (4.30)
$$

We follow Froissart’s idea to evaluate the value of the characteristic impact parameter $b_0$, namely, the value of $b_0(x)$ can be found from the following equation

$$
\frac{\Omega(x, r_{1,t}, r_{2,t}; b_0(x))}{2} = 1. \quad (4.31)
$$
Indeed, for \( b_t > b_0 \frac{\Omega}{2} < 1 \) the full formula gives less than the first term of the expansion, while for \( b_t < b_0 \frac{\Omega}{2} > 1 \), the elastic amplitude for the fixed value of the impact parameter is less than 1. Using Eq. (3.19) we obtain the solution of Eq. (4.31) in the form

\[
b_0^2 = -r_{2,t}^2 (z_2 \bar{z}_2) + \frac{\alpha_s}{N_c} \sqrt{\pi \left( N_c^2 - 1 \right)} \frac{r_{1,t} r_{2,t}}{2} \sqrt{I_0 \left( 2 \sqrt{\xi(r_{1,t} r_{1,t}) \ln(1/x)} \right)}
\]

(4.32)

see Eq. (3.20) for all notation.

One can see that Eq. (4.32) leads to \( b_0^2 \rightarrow e^{2\sqrt{\xi(r_{1,t} r_{1,t}) \ln(1/x)}} \) at \( x \rightarrow 0 \) which means that \( b_0(x) \) increases faster than any power of \( \ln(1/x) \).

One can see that \( b_0^2 \) becomes negative at rather large values of \( x \). It reflects the fact that Eq. (4.31) does not have a solution at all values of \( x \). In other words, \( \Omega/2 < 1 \) even at \( b_t = 0 \) for low energies. However, it should be stressed that Eq. (4.31) does have a solution at high energies which we are actually dealing with in this paper.

Substituting Eq. (4.32) into Eq. (4.29) we obtain

\[
\sigma_{tot}^{dd} < 2\pi \left( 2 b_0^2(x) + r_{2,t}^2 (z_2 \bar{z}_2) \right)
\]

(4.33)

with \( b_0 \) of Eq. (4.32). Eq. (4.32) is in striking contradiction with the Froissart theorem which states that \( \sigma_{tot}^{dd} \ll \ln^2(1/x) \) (see Ref. [33] for more details on the Froissart theorem for photon interaction.)

\[
b_0 \gg \frac{1}{2 m_{\pi}}
\]

In this case for \( b_t > b_0 > \frac{1}{2 m_{\pi}} \) the integral over \( \kappa \) in Eq. (2.15) is concentrated at \( \kappa \rightarrow 2 m_{\pi} \) with \( \kappa - 2 m_{\pi} \approx 1/b_t \). Since \( 2 m_{\pi} a \ll 1 \) we expand \( J_1 \) function, namely \( J_1(\kappa a) = \frac{1}{2} \kappa a \). Since we are interested only in large \( b_t \) behaviour of the opacity \( \Omega(b_0 \gg \frac{1}{2 m_{\pi}}) \) we replace \( \kappa^2 \) under integral by \((2 m_{\pi})^2 \). The use of the asymptotic behaviour of McDonald’s function as well as the simplifications, mentioned above, leads to overall accuracy \( 1/b_t \) in the pre-exponential factor, which is enough to obtain the unitarity bound. It worthwhile mentioning that in our numerical calculation the integral of Eq. (2.15) was computed without any approximations.

Finally we have the following estimate for the integral of Eq. (2.15)\(^8\)

\[
\sigma_{dipole}^{BA} = -\pi \alpha_s^2 \frac{N_c^2 - 1}{2 N_c^2} \left( 2^2 \pi \right) (2 m_{\pi})^2 \int_{2 m_{\pi}}^{\infty} \kappa \ln(1/x) K_0(\kappa b_t) \]

(4.34)

\[
= \pi \alpha_s^2 \frac{N_c^2 - 1}{2 N_c^2} \left( 2^2 \pi \right) (2 m_{\pi})^3 \frac{1}{b_t} K_1(2 m_{\pi} b_t) \]

(4.35)

\[
\rightarrow \pi \alpha_s^2 \frac{N_c^2 - 1}{2 N_c^2} \left( 2^2 \pi \right) (2 m_{\pi})^3 \sqrt{\frac{\pi}{4 m_{\pi} b_t^3}} e^{-2 m_{\pi} b_t} \]

(4.36)

\(^8\)The integral \( \int_{2 m_{\pi}}^{\infty} z K_0(z) dz = K_1(2 m_{\pi}) \). It follows directly from the differential equation for \( K_0 \), namely \( \frac{d}{dz}(z K_0(z)) = -z K_0(z) \) which should be integrated over \( z \). Recalling that \( -\frac{d}{dz} K_0(z) = K_1(z) \) we obtain the above integral. The alternative way is to use a combination of equations 6.561(8) and 6.561(16) from Ref. [39].
where Eq. (4.36) gives the asymptotic behaviour at large $b_t \gg 1/(2 m_\pi)$). Namely, this is the expression we will use for the estimates of the value of $b_0$ in this case. Substituting Eq. (4.36) in Eq. (2.15) and Eq. (3.27) we find the solution to Eq. (4.31), namely

$$b_0^{\text{exp}}(x) = \frac{1}{2 m_\pi} \ln \left( \pi \frac{\alpha_S^2}{4 N_c^2} \frac{N_c^2 - 1}{4 N_c^2} (r_{1,t}^2 r_{2,t}^2)(2 m_\pi)^2 \sqrt{\frac{\pi}{4 m_\pi b_0^{\text{exp}}(x)}} x G(x, r_{1,t}^2, r_{2,t}^2) \right) \quad (4.37)$$

Eq. (4.37) is still an equation for $b_0^{\text{exp}}$ which has the asymptotic solution at low $x$:

$$b_0^{\text{exp}}(x) = \frac{1}{2 m_\pi} \ln \left( \pi \frac{\alpha_S^2}{4 N_c^2} \frac{N_c^2 - 1}{4 N_c^2} (r_{1,t}^2 r_{2,t}^2)(2 m_\pi)^2 \sqrt{\frac{\pi}{2}} x G(x, r_{1,t}^2, r_{2,t}^2) \right) \quad (4.38)$$

One can see two important differences between this case and the case that we have considered previously:

1. $b_0$ of Eq. (4.38) grows only logarithmically as a function of energy. From Eq. (3.20) we conclude that $b_0^{\text{exp}} \propto \sqrt{\ln(1/x)}$;

2. the second term in Eq. (4.29) gives a small contribution which does not depend on energy.

Therefore, in this kinematic region the unitarity bound has a form

$$\sigma_{\text{tot}}^{\text{dipole-dipole}} < 2\pi \left( b_0^{\text{exp}}(x) \right)^2 \quad (4.39)$$

with $b_0^{\text{exp}}$ from Eq. (4.38).

This equation reproduces the classical Froissart result [28], namely, the fact that the total cross section can increase only logarithmically. This is the kind of energy behaviour we expect for DIS or hadron-hadron collisions. However, we would like to draw your attention to the fact that we obtain

$$\sigma_{\text{tot}}^{\text{dipole-dipole}} \leq \frac{2\pi}{(2 m_\pi)^2} \ln(1/x) \quad ; \quad \sigma_{\text{tot}}^{\text{hadron-hadron}} \leq \frac{2\pi}{(2 m_\pi)^2} \ln^2 s \quad (4.40)$$

while the unitarity bound for the hadron-hadron cross section has $\ln^2 s$ - behaviour ($\sigma_{\text{tot}}^{\text{hadron-hadron}} \leq \frac{2\pi}{(2 m_\pi)^2} \ln^2 s$).

It is worthwhile mentioning that Eq. (4.40) holds in the wide range of the photon virtualities which we will define below.

**Predictions:**

Comparing Eq. (4.33) and Eq. (4.39), one can see that in a wide range of energies where $b_0(x) \lesssim 1/2 m_\pi$ the photon-photon scattering shows an exponential ($\propto e^{\sqrt{a \ln(1/x)}}$) behaviour as a function of $\ln(1/x)$, in striking contradiction with the DIS or/and hadronic processes. However, for higher energies $b_0^{\text{exp}}(x)$ reaches the value of $1/2 m_\pi$ or $1/m_{\text{glueball}}$. For higher energies the unitarity bound becomes the one of Eq. (4.39). The numerical evaluation shown in
Fig. 4 illustrate the fact that the kinematic region of an exponential increase is wide, especially if we believe that the non-perturbative corrections will only appear at small masses in t-channel. Therefore, we find that $\gamma^* - \gamma^*$ scattering shows quite different behaviour than DIS and hadronic processes at all accessible energies (see Fig. 4). However, if the typical mass in t-channel is rather the mass of a glueball (see Ref. [42]) the non-perturbative corrections will stop the exponential increase as $e^{\sqrt{a \ln(1/x)}}$ at $x \approx 10^{-5}$.

It is interesting to notice that the value of $b_0(x)$ turns out to be larger at larger value of $Q^2$ in the region of low $x$. The reason for such behaviour is the fast increase of the gluon density at larger values of $Q^2$ which prevails the suppression due to extra factor $1/Q$ in Eq. (4.32). From Fig. 4 one can see that $b_0(Q^2 = 20 GeV^2) < b_0(Q^2 = 40 GeV^2)$ at $x \leq 10^{-7}$.
5 Total $\gamma^* - \gamma^*$ for accessible energies

Using the master formula of Eq. (1.1) with the dipole-dipole cross section given by Eq. (4.28) we calculate the $\gamma^* - \gamma^*$ total cross sections at accessible range of energies. The results of calculations are presented in Fig. 5. We fix the virtuality of one of the photons at $Q_2^2 = 4 GeV^2$ and calculate the cross section at different values of $Q_1^2$. It is essential to recall that we discuss $\gamma^* - \gamma^*$ scattering in the DGLAP dynamics and we have to fix large values for virtualities of both photons. $Q_2^2 = 4 GeV^2$ corresponds to $r_2^2 \approx 0.2 fm$ which is smaller than the electromagnetic radius of pion ($R_\pi = 0.66 fm$). Therefore, we can apply perturbative QCD to our process.

In Fig. 7 we also show the experimental data for the $\gamma^* - \gamma^*$-process since there is no experimental information about the values of the cross sections for $\gamma^* - \gamma^*$-scattering for large but different photon virtualities. However, the main dependence of the cross section is on the largest virtualities and we can hope that the data on $\gamma^* - \gamma$ reaction is not very different from $\gamma^* - \gamma^*$ one.

One can see from Fig. 7 that our predictions are not in contradiction with available but poor experimental data. We see in Fig. 8 that data with one real photon overshoot our predictions. Actually, there are more data on $\gamma^* - \gamma$ reaction but they are presented in the form of photon structure function. We do not want to recalculate the cross section using these data since we, being theorists, are not entitled to put experimental errors for these reconstructed data. We would like to mention once more that this comparison with the experiment could be considered only as illustrative one showing that we obtain a reasonable estimates for the value of the cross sections. The fact that the data with large but equal virtualities are less than our prediction is understandable since in our approach the cross sections for such processes do not have an extra enhancement due to the gluon structure function.

Therefore, we can view Fig. 8 as an argument that our predictions do not contradict the current experimental data and as the reason for our expectations that future experiments will provide us with data which we will be able to compare with our predictions.

It should be mentioned that for serious comparison with the experimental data we have to calculate the power-like corrections to high energy behaviour discussed in this paper. These corrections are calculable for $\gamma^* - \gamma^*$ scattering and they can be described as the exchange of quark-antiquark pair in $t$-channel (so called “box” diagram of Fig. 6). The simple “box” diagram without gluon emission falls down as $1/W^2$ where $W$ is the energy of $\gamma^* - \gamma^*$ scattering. However, the gluon emission slow down this decrease and, therefore, such corrections could be important at sufficiently high energies.

It is instructive also to compare the realistic calculation with the unitarity bound (see Fig. 8). To calculate the unitarity bound we use Eq. (1.1) where we substitute

$$\int d^2 b_t \sigma_{a,b}^{dd}(x, r_1^2, r_2^2; b_t) = 2\pi \left( 2b_0^2(x) + r_2^2(z_2 \bar{z}_2) \right). \quad (5.41)$$

One can see that the unitarity bound considerably overestimates the value of the cross section.
Figure 5: Energy behaviour of total $\gamma^* - \gamma^*$ cross section.

Figure 6: The picture of interaction of two photons with virtualities $Q_1$ and $Q_2$ due to quark-antiquark pair exchange (so called “box” diagram).
Figure 7: Energy behaviour of total $\gamma^* - \gamma^*$ cross section for low energies and experimental data. Squares denote the L3 data [35] while the triangles mark OPAL data [36]. Circles label data taken from [37].
6 Summary

We can summarize our approach in the following way. The kinematic region which we study in this paper is the high density QCD region. In this region we have the system of partons at short distances at which $\alpha_s$ is small, but the density of partons has become so large that we can not apply the usual methods of pQCD. The important method to deal with hdQCD is a Glauber- Mueller approach, which gives the simplest approximation for the high parton density effects. Developing the Glauber- Mueller approach, we obtained the following results.

- Both DGLAP and BFKL equations are linear evolution equations predicting a steep growth of cross sections as a function of energy. However, it is believed that unitarity holds for all physical processes. At high energies it manifests itself as a suppression of the growth of the cross section. At the saturation scale $Q_s(x)$ nonlinear effects set in. These effects are due to formation of a high density parton system.
- In this paper for the first time the Glauber - Mueller approach has been developed for

\[ \sigma(\gamma^* \gamma^*) \, (\text{n barn}) \]

\[ Q_1^2 = 20 \text{ GeV}^2; \quad Q_2^2 = 4 \text{ GeV}^2 \]
the case of virtual photon - photon scattering. It allows us to estimate the saturation scale where the transition occurs from the low density to the high parton density regime. The estimate is made from the equation \(( r_1 > r_2)\)

\[
\Omega(b = 0, r_{1,saturation}, r_2)/2 = 1 \tag{6.42}
\]

The solution of this equation is shown in Fig. 9.

The solution to Eq. (6.42) is proportional to \(r_{1,saturation} \propto r_{2,t}(xG(x, r_{1,saturation}, r_{2,t}))^{-1}\).

It is not surprising that the value of \(r_{1,saturation}\) decreases as function of \(Q_s^2\) as one can see in Fig. 9. At first sight it looks strange that the value of the saturation scale \(Q_s^2 = 4/r_{saturation}^2\) is rather large. Indeed, for \(x = 10^3\) and \(Q_s^2 = 4 \text{ GeV}^2\) the value of \(Q_s^2 \approx 70 \text{ GeV}^2\) is much larger than expected \(Q_s^2 \approx 1 - 2 \text{ GeV}^2\) for proton.
To understand this difference we take the parameterization of the gluon structure function for proton in the form of Eq. (5.20), namely $xG(x, Q^2) = G_0 I_0(2 \sqrt{\xi(2/Q, R_p)} \ln(1/x))$. $R_p$ is a proton radius which in this estimate we can take $R^2 = 10 \text{GeV}^{-2}$. $G_0$ is equal 0.136. One can obtain

$$\frac{Q^2_1(\gamma^* - \gamma^*)}{Q^2_2(\gamma^* - \text{proton})} \propto Q^2_2 R_p^2 (1/G_0) \approx 70.$$  

Therefore, we claim that the large value of the saturation momentum is one of the interesting features of the $\gamma^* - \gamma^*$ scattering at high energy.

- We note that the gluon interaction leads to power-like decrease of the opacity ($\Omega$) in Glauber - Mueller formula as a function of the impact parameter ($b$), namely $\Omega \propto 1/b_t^4$. It turns out that because of this behavior the $\gamma^* - \gamma^*$ cross section has a wide range of energy where it increases faster than any power of $\ln(1/x)$ in remarkable contradiction with hadron - hadron and deep inelastic cross sections, which cross sections can have only $\ln^2 W$ growth with energy [28]. This fast rise of the $\gamma^* - \gamma^*$ cross section continue up to energies at which the typical impact parameter ($b_0(x)$) will reach the value of $1/2 m_\pi$ ($b_0 = 1/2 m_\pi$), see Fig. 4.

- The influence of this power-like $b_t$ behaviour on unitarity bound is studied. This bound is calculated to give an estimate for the energy behavior of the cross section.

- It is shown that non-perturbative contributions are needed even for the case of photon-photon scattering with large virtualities of both photons in order to describe the large $b_t$-behavior of the dipole-dipole scattering amplitude.

- We found out that the unitarity bound for dipole-dipole cross section for very high energies is $\sigma(\gamma^* - \gamma^*) \leq \frac{2\pi}{(2m_\pi)^2} \ln(1/x)$. This result can be translated in the unitarity bound for $\gamma^* - \gamma^*$ cross section after integration over $r_{1,t}$ and $r_{2,t}$ in Eq. (1.1). For $Q^2_2 \ll Q^2_1 \leq Q^2_{1,\text{sat}} = 4/\nu^2_{1,\text{saturation}}$ we obtain:

$$\sigma_{T,T}(\gamma^* - \gamma^*) \leq \sum_{a,b} \left( \frac{4\alpha_{em}}{\pi} \right)^2 Z_a^2 Z_b^2 \ln(Q^2_{1,\text{sat}}/Q^1_1) \ln(Q^2_{1,\text{sat}}/Q^2_1) \left( \frac{2\pi}{(2m_\pi)^2} \right) \ln(1/x);$$

$$\sigma_{T,L}(\gamma^* - \gamma^*) \leq \sum_{a,b} \left( \frac{4\alpha_{em}}{\pi} \right) \left( \frac{6\alpha_{em}}{\pi} \right) Z_a^2 Z_b^2 \ln(Q^2_{1,\text{sat}}/Q^1_1) \left( \frac{2\pi}{(2m_\pi)^2} \right) \ln(1/x);$$

$$\sigma_{L,T}(\gamma^* - \gamma^*) \leq \sum_{a,b} \left( \frac{4\alpha_{em}}{\pi} \right) \left( \frac{6\alpha_{em}}{\pi} \right) Z_a^2 Z_b^2 \ln(Q^2_{1,\text{sat}}/Q^2_1) \left( \frac{2\pi}{(2m_\pi)^2} \right) \ln(1/x);$$

$$\sigma_{L,L}(\gamma^* - \gamma^*) \leq \sum_{a,b} \left( \frac{6\alpha_{em}}{\pi} \right)^2 Z_a^2 Z_b^2 \left( \frac{2\pi}{(2m_\pi)^2} \right) \ln(1/x); \quad (6.43)$$

In Eq. (6.43) for transverse polarized photon we used the logarithmic approximation in the integral over $r_t$. Indeed, $|\Psi_T|^2 \propto 1/r_t^2$ and it should be integrated from $4/Q^2_{\text{sat}}$ to
Taking into account that $Q_{\text{sat}}^2 \propto xG \propto e^2 \sqrt{x\xi(r_1,r_2,t)} \ln(1/x)$ (Eq. (3.21)) one can see that

$$\sigma_{T,T}(\gamma^* - \gamma^*) \leq \frac{C_{T,T}}{(2m_\pi)^2} \ln^2(1/x); \quad (6.44)$$

$$\sigma_{T,L}(\gamma^* - \gamma^*) \leq \frac{C_{T,L}}{(2m_\pi)^2} \ln^2(1/x); \quad (6.45)$$

$$\sigma_{L,L}(\gamma^* - \gamma^*) \leq \frac{C_{L,L}}{(2m_\pi)^2} \ln^2(1/x); \quad (6.46)$$

Therefore, only $\sigma_{T,T}$ has the same energy dependence of the unitarity bound as hadron-hadron cross section.

- Our approach shows that the non-perturbative corrections at large $b_t$ should be taken into account in the Born cross section. Another way to treat this result is to say that the non-perturbative corrections can be taken into account only in the initial conditions as was discussed in Refs. [29, 30]. We do not see that such corrections are needed in the kernel of the non-linear evolution equation [38] as was argued in Refs. [21, 22, 23, 24].

The estimates at what energies such corrections will enter the game are presented and discussed.

- Numerical calculations are performed for the value of the total cross section for accessible energies and virtualities. These predictions will be checked soon with new coming data.

We hope that this paper will stimulate further experimental study of $\gamma^* - \gamma^*$-processes which can give a very conclusive information on the saturation kinematic region in QCD.

**Acknowledgments:** We would like to thank the DESY Theory Group for their hospitality and creative atmosphere during several stages of this work.

We wish to thank Jochen Bartels, Errol Gotsman and Uri Maor for very fruitful discussions on the subject.
