ABSTRACT

To ensure error-free duplication of all (epi)genetic information once per cell cycle, DNA replication follows a cell type and developmental stage specific spatio-temporal program. Here, we analyze the spatio-temporal DNA replication progression in (un)differentiated mouse embryonic stem (mES) cells. Whereas telomeres replicate throughout S-phase, we observe mid S-phase replication of (peri)centromeric heterochromatin in mES cells, which switches to late S-phase replication upon differentiation. This replication timing reversal correlates with and depends on an increase in condensation and a decrease in acetylation of chromatin. We further find synchronous duplication of the Y chromosome, marking the end of S-phase, irrespectively of the pluripotency state. Using a combination of single-molecule and super-resolution microscopy, we measure molecular properties of the mES cell replicon, the number of replication foci active in parallel and their spatial clustering. We conclude that each replication nanofocus in mES cells corresponds to an individual replicon, with up to one quarter representing unidirectional forks. Furthermore, with molecular combing and genome-wide origin mapping analyses, we find that mES cells activate twice as many origins spaced at half the distance than somatic cells. Altogether, our results highlight fundamental developmental differences on progression of genome replication and origin activation in pluripotent cells.

INTRODUCTION

DNA replication, together with DNA transcription and repair, is a fundamental nuclear metabolic process. Complete and error-free genome duplication once every cell cycle is essential for genome integrity and maintenance. In eukaryotic cells, DNA replication can be subdivided in two main stages: recognition and subsequent licensing of origins of replication (ORIs) at the transition from mitosis (M-phase) to the gap 1 (G1) phase (1,2), and the activation of only a subset of these origins at the beginning of the synthesis (S) phase. The latter is eventually followed by the duplication of the (epi)genetic information by the multi-protein DNA synthesis complex (replisome) (3,4). After the initial unwinding of the DNA replication bubble at the origin of replication, the replisome ensures the semi-conservative duplication of the underlying DNA template (reviewed in (5)). Many features of DNA replication organization share high similarities between different species, including yeast, fruit flies, mice and humans (6–10), and homologues for the key factors involved have been identified in most of these species (3). Genome duplication follows a spatio-temporal program generally correlating with transcriptional activity, specific epigenetic marks and 3D genome architecture (11). Cyto logical methods relying on the detection of components of the replisome or nascent DNA via incorporation of modified nucleotides, allow the in situ visualization of newly synthesized DNA and sites of ongoing DNA replication (replisome foci (RFi)). These replication foci form distinct spatial patterns, characterized by the dynamic intra-nuclear distribution of the replication signals during S-phase progression (5–7,12–14). In metazoan cells, three main patterns are observed, at early (I), mid (II) and late (III) S-phase, corresponding to the replication of euchromatin, facultative and constitutive heterochromatin, respectively (10,15,16).

Fluorescence recovery after photobleaching (FRAP) experiments showed the de novo assembly of replicosomes adjacent to previously activated sites (17), suggesting that, instead of persisting as permanent factories throughout S-phase (18), replicosomes are activated in a ‘next in-line’ manner (domino model). Hence, complete DNA replication depends on the initial stochastic activation/spontaneous firing of a few origins with high firing probability within euchromatic regions of each chromosome and the subsequent domino-like activation of adjacent origins with decreasing firing probability during S-phase progression (19–22).

In early autoradiographic fiber studies of single DNA molecules it was observed that replicons resulted from individual initiation events at origins of replication, which are organized and activated in clusters of, on average, 1 Mb in size and consisting of 2–9 smaller replicons of 100–200 kb (6,23,24). DNA halo analysis showed that these replicon sizes are in good agreement with measured sizes of chromatin loops. Hence, loop structures, potentially mediated by cohesins or functionally related proteins (25,26), represent the DNA element that defines replicons as functional unit in the DNA replication context (reviewed in (27)). Labeling cells with modified nucleotides revealed that the replicon clusters observed on DNA fibers become visible as the before-mentioned replication foci in interphase nuclei (15). With higher optical resolution levels, the number of replication foci measured in cells increased and each replication nanofocus in somatic mammalian cells was shown to be equivalent to a replicon unit (28,29). Besides loop structures, chromatin signatures and the associated changes in chromatin structure and accessibility, influence licensing and activation of origins of replication and, thus, replication timing programs in mammalian cells (30). In that regard, major changes in DNA replication timing have been correlated with changes in histone acetylation levels, as histone hyperacetylation was shown to advance origin firing and DNA replication timing (31–34).

DNA replication studies in early developmental stages of Drosophila and Xenopus embryos revealed very rapid cell divisions with no gap phases and short S-phase duration (35–37). The latter is based on high origin activation levels, short inter-origin distances and concomitant differences in replicon sizes (36–38). While early developing mouse cells do not exhibit such fast cell division rates, they are characterized by short gap phases and the (almost complete) absence of transcription in the first zygotic cleavage stage (3,35–37,39–41). Additionally, specific spatial replication patterns already exist at the one-cell stage in mouse embryos (42) and replication programs of differentiating cells undergo large rearrangements during lineage commitment (43,44).

Here, we analyzed the replication dynamics in pluripotent mouse embryonic stem (mES) cells by characterizing the replication timing program and the replicon organization, and ultimately comparing it to known features of mouse somatic cells. We demonstrate that mES cells exhibit a distinct replication timing in comparison to differentiated and somatic cells, marked by early/mid replication of pericentromeric heterochromatin. We further show that this changes during mES cell differentiation when pericentromeric heterochromatin becomes late replicating. This major change correlates with differences in chromatin compaction and histone acetylation levels and can be emulated by targeting histone deacetylases to pericentromeric heterochromatin. Analysis of the replication timing of (sub)chromosomal elements, revealed in addition a synchronous replication of the Y chromosome that concomitantly marks the end of S-phase in mES cells, as well as in differentiated and somatic cells. Using a combination of molecular and super-resolution imaging techniques, we characterized the mES cell replicon, the essential functional unit of DNA replication. We found by DNA combing and genome-wide origin profiling data analyses that mES cells activate more origins of replication compared to somatic cells resulting in shorter inter-origin distances, which in turn leads to smaller replicon sizes. Furthermore, in contrast to human somatic cells, duplication of the mES cell genome relies on a substantial amount of single (unidirectional) replication forks.

MATERIALS AND METHODS

Expression constructs

To generate the expression vector containing a fusion protein of eGFP and human HDAC1 (peGFP-hHDAC1, pc2447), hHDAC1 was amplified from human cDNA with the following primers containing BglII and Eco47III restriction enzyme sites: fw: 5′-AAAGATCTAGCAAGATGCGCCAGACGACG-3′ and rev: 5′-AAAGCGCTGGGCAAACCTTGACCTC-3′. PCR amplification and pcR2.1-TOPO vector (Thermo Fisher Scientific, Walhalm, MA, USA) were double digested with BgIII and Eco47III and ligated. The final peGFP-hHDAC1 was generated by double digesting pcR2.1-TOPO-hHDAC1 with BgIII and XhoI and hHDAC1 was inserted into the BglIII/SalI digested backbone vector peGFP-C1 (pc0592, Clontech Laboratories, Mountain View, CA, USA). SalI and XhoI form compatible ends that allow ligation. The final plasmid eGFP-hHDAC1 was verified by restriction enzyme digest, sequencing and enzymatic activity was analyzed via histone acetylation stainings (H4K5ac and H4K8ac, Figure 3B) in transfected cells.

All plasmid characteristics are summarized in Supplementary Table S1.

Cell culture, differentiation and transfection

All cells were mycoplasma free. J1 (45) and E14 (46) mouse embryonic stem cell lines were cultured in Dulbecco’s modified Eagle’s medium (DMEM) high glucose (Cat. No.: D6429, Sigma-Aldrich Chemie GmbH, Steinheim, Germany) supplemented with 15% fetal calf serum (FCS), 1× non-essential amino acids (Cat. No.: M7145, Sigma-Aldrich Chemie GmbH, Steinheim, Germany), 1× penicillin/streptomycin (Pen/Strep) (Cat. No.: P4333, Sigma-Aldrich Chemie GmbH, Steinheim, Germany), 1× 1-glutamine (Cat. No.: G7513, Sigma-Aldrich Chemie GmbH, Steinheim, Germany), 0.1 mM betamercaptoethanol (Cat. No.: 4227, Carl Roth, Karlsruhe, Germany), 1000 U/ml recombinant mouse LIF (Millipore) and 2i (1 μM PD032591 and 3 μM CHIR99021 (Cat. Nos.: 1408 and 1386 respectively, Axon Medchem, Netherlands)) on gelatin-coated culture dishes (0.2% gelatin; Cat. No.:
G2500, Sigma-Aldrich Chemie GmbH, Steinheim, Germany). Culture medium was changed every day and cells were split every 2 days.

Mouse embryonic fibroblasts (MEF W8 (47)) and mouse myoblasts (C2C12 (48)) were cultured in DMEM high glucose supplemented with 1× L-glutamine, 1 μM gentamicin (Cat. No.: G1397, Sigma-Aldrich Chemie GmbH, Steinheim, Germany) and 10% and 20% FCS, respectively.

Mouse primary fibroblasts were isolated from ear tissue of adult mice (C57BL/6) sacrificed according to the animal care and use regulations (Government of Hesse, Germany). The tissue was shaken at 37°C with 2 mg/ml collagenase NB8 (Serva Electrophoresis, Heidelberg, Germany) in DMEM supplemented with 1× Pen/Strep and vortexed repeatedly. Dissociated ear tissue was pipetted through a cell strainer (Cat. No.: 352235, Corning, NY, USA), single cells were plated on a gelatin-coated (0.2%) dish and cultivated in DMEM supplemented with 10% FCS and 1 μM gentamicin at 37°C and 5% CO₂.

Differentiation of naïve pluripotent stem cells was performed as previously described (49) with the exception that the differentiation medium contained 10 μM retinoic acid (Cat. No.: R2625, Sigma-Aldrich Chemie GmbH, Steinheim, Germany).

For live cell experiments, J1 mES cells were co-transfected with plasmids encoding for mRFP-tagged hPCNA (50) and MaSat-GFP (51) using AMAXA nucleofection (B016, Amaxa Nucleofector II, Lonza Ltd., Basel, Switzerland) and plated on gelatin-coated p35 dishes containing a glass bottom that allowed for optical imaging. For HDAC1 targeting to chromocenters, J1 mES cells were co-transfected with plasmids encoding for GBP-MaSat (52) and eGFP-hHDAC1/eGFP-C1 using AMAXA as described above. Twenty-four hours after transfection, cells were pulse chased and Edu, PCNA and histone modifications were detected as described below.

All cell line and plasmid characteristics are summarized in Supplementary Tables S1 and S2, respectively.

DNA replication labeling and (immuno)fluorescent visualization

For immunostaining experiments, cells were grown on glass coverslips coated with 0.2% gelatin.

To visualize and analyze progression of DNA replication, cells were labeled with 10 μM 5-ethyl-2-deoxyuridine (EdU) for 12 min, chased for varying times with medium supplemented with 50 μM thymidine, fixed with 3.7% formaldehyde/1× phosphate-buffered saline (PBS) (Cat. No.: F8775, Sigma-Aldrich Chemie GmbH, Steinheim, Germany) for 10 min and permeabilized with 0.5% TritonX100 in 1× PBS for 20 min. All washing steps were performed with PBS-T (1× PBS/0.02% Tween-20). For detection of PCNA, cells were further incubated for 5 min in ice-cold methanol on ice for antigen retrieval. Blocking (1% bovine serum albumin, 0.5% fish skin gelatin and 0.02% Tween-20 in 1× PBS) was performed for 30 min at room temperature. EdU was detected using the Click-IT assay as described by the manufacturer (1:200 3-azido-7-hydroxycoumarin, 1:1000 6-carboxyfluorescin (6-FAM azide) or 1:2000 5/6-Sulforhodamine azide; Cat. No.: 7811, 7806 and 7776 respectively, Carl Roth, Karlsruhe, Germany). Primary mouse anti-PCNA and secondary donkey anti-mouse IgG conjugated with Cy3 were diluted in blocking buffer and incubated for 1 h at room temperature. DNA was counterstained with DAPI (4',6-diamidino-2-phenylindole, 10 μg/ml, Cat. No.: D27802, Sigma-Aldrich Chemie GmbH, Steinheim, Germany) for 10 min and samples were mounted in Mowiol4-88 (Cat. No.: 81381, Sigma-Aldrich Chemie GmbH, Steinheim, Germany) containing 2.5% DABCO (1,4-diazabicyclo[2.2.2]octane, Cat. No.: D27802, Sigma-Aldrich Chemie GmbH, Steinheim, Germany).

To analyze replication foci in 3D super-resolution microscopy (3D-SIM), samples were prepared as described (28,53). Briefly, cells were seeded on gelatin-coated high precision coverslips (Cat. No.: LH22.1, Karl Roth, Karlsruhe, Germany), grown for 6–8 h to ensure attachment but avoid 3D colony formation, and labeled with 100 μM 5-bromo-2-deoxyuridine (BrdU) for 25 min followed by a thymidine chase (50 μM) of 0, 30 or 60 min. Fixation and pretreating treatments were performed as described above. BrdU was detected with a rat anti-BrdU antibody diluted in buffer consisting of a 1:1 mixture of blocking and 2× DNase I reaction buffer (60 mM Tris/HCl pH 8.1, 0.66 mM MgCl₂, 1 mM beta-mercaptoethanol) and 25 U/ml DNase I (Cat. No.: D5025, Sigma-Aldrich Chemie GmbH, Steinheim, Germany). Samples were incubated for 1 h at 37°C and DNase I digestion was stopped by washing with PBS-TE (PBS-T with 1 mM EDTA). PCNA detection was done as described above. After secondary antibody incubation with donkey anti-rat IgG AlexaFluor 488 and donkey anti-mouse IgG AlexaFluor 594, samples were mounted in Vectashield (Invitrogen, Carlsbad, CA, USA).

All nucleotide and antibody characteristics are summarized in Supplementary Tables S3 and S4, respectively.

Immunofluorescence

For pluripotency marker detection, cells were grown, fixed, permeabilized and blocked as described for DNA replication visualization. Primary mouse anti-Oct3/4, rabbit anti-Sox2 and secondary goat anti-rabbit IgG Alexa647 and goat anti-mouse IgG Alexa488 were diluted in blocking buffer and applied for 1 h at room temperature.

For histone modification analysis, cells were grown, Edu labeled, fixed, permeabilized and blocked as described above. Edu was detected as described by the manufacturer (1:1000 6-FAM azide). The following primary and secondary antibodies were diluted in blocking buffer: mouse anti-H3K9ac, rabbit anti-H3K9m3, rabbit anti-H4K8ac, rabbit anti-H4K8ac, donkey anti-mouse IgG Cy3 and donkey anti-rabbit IgG Cy3. Incubation was done for 1 h at room temperature.

DNA counterstaining and mounting using Mowiol was performed as described above.

All nucleotide and antibody characteristics are summarized in Supplementary Tables S3 and S4, respectively.
Major satellite (MaSat) polydactyl zinc finger (PZF) fixation

Since transfected MaSat-GFP (pc1803 and (51)) is not fixable with standard formaldehyde or methanol fixation protocols, we made use of a gradient fixation protocol combined with a simultaneous mild permeabilization on ice. Twenty-four hours after transfection with MaSat-GFP, J1 mES cells were put on ice and 3.7% formaldehyde. Twenty-four hours after transfection with MaSat-GFP, J1 mES cells were put on ice and 3.7% formaldehyde/1× PBS with 0.1% Nonidet P 40 Substitute (Cat. No.: 74385, Sigma-Aldrich Chemie GmbH, Steinheim, Germany) was added to the medium to achieve a final concentration of 0.1% formaldehyde. After 10 min, formaldehyde concentration was increased to 0.2% and incubated for 10 min. This procedure was repeated 6 times (0.5%, 1%, 1.5%, 2%, 2.5%, 3% formaldehyde). Increasing formaldehyde concentration to 1.5% was performed with a 0.1% Nonidet P 40 substitute containing formaldehyde stock solution. In a final step, the medium/formaldehyde mixture was replaced by 3.7% formaldehyde (10 min incubation) and exchanged with PBS-T.

Molecular combing

Molecular combing experiments were performed using the FiberPrep® kit (Cat.No.: EXTR-001, Genomic Vision, Bagneux, France) and as described before (54). Briefly, J1 mES cells were pulse labeled for 15 min with 10 μM 5-chloro-2′-deoxyuridine (ClUdU), washed twice with pre-warmed PBS, labeled with 100 μM 5-iodo-2′-deoxyuridine (IdU) for 15 min, washed extensively and chased for 1 h with 50 μM thymidine. Cells were subsequently embedded in low-melting point agarose, genomic DNA was isolated by proteinase K (Cat. No.: 7528, Carl Roth, Karlsruhe, Germany) digestion and single high molecular weight DNA molecules were stretched on silanized glass coverslips (Cat. No.: COV-002-RUO, Genomic Vision, Bagneux, France), using the FiberComb®-Molecular Combing System (Cat. No.: MCS-001, Genomic Vision, Bagneux, France) as described by the manufacturer. Incorporated nucleotides and single stranded DNA were detected using mouse anti-BrDU/IdU, rat anti-BrDU/CdU and mouse single-stranded DNA (IgG2a) primary antibodies and goat anti-mouse IgG Chromeo 546, donkey anti-rat IgG AlexaFluor 488 and goat anti-mouse IgG2a AlexaFluor 647 secondary antibodies.

All nucleotide and antibody characteristics are summarized in Supplementary Tables S3 and S4, respectively.

Probe generation, metaphase and (Repli-)FISH (fluorescence in situ hybridization)

Probes against major satellites, minor satellites and telomeres were generated as described in (55).

The Y chromosome probe was generated via DOP-PCR (degenerated oligonucleotide-primed-PCR). For template stock generation, PCR reactions contained mouse Y chromosome-specific template DNA (kind gift of Prof. Dr. Diane Krause, Yale University School of Medicine), 2 μM 6A1 primer (5′-CCGGACTCUGANNNNNTACA CC-3′), 0.25 mM dNTPs and 2.5 U Taq polymerase in 1× PCR buffer (10 mM Tris/HCl pH 8.3, 50 mM KCl and 1.5 mM MgCl2) and cycling conditions were set to (45″ at 94°C, 45″ at 15°C, 12″ at 37°C) × 1, (40″ at 94°C, 45″ at 37°C, 4′ at 66°C) × 5 and (40″ at 94°C, 45″ at 54°C, 4′ at 66°C) × 24. Y chromosome template DNA was labeled with biotinylated nucleotides (55) in the following reaction: template stock DNA was mixed with a nucleotide mixture containing unlabeled nucleotides (0.2 mM each dATP, dCTP and dGTP with 0.1 mM dTTP), biotinylated dUTPs (0.1 mM biotin-16-dUTPs), 2 μM 6A1 primer, 2.5 U Taq polymerase and 1× PCR buffer. Cycles were set to (5′ at 94°C) × 1, (30′ at 94°C, 30″ at 54°C, 90″ at 72°C) × 35 and (5′ at 72°C) × 1.

Metaphase FISH and co-visualization of DNA replication and DNA probes were performed as previously described (55), using rabbit anti-digoxigenin, anti-rabbit IgG Cy3 antibodies and Streptavidin Alexa488 or Streptavidin Cy5 (1:500, Cat. No.: S11223 and SA1011, Thermo Fisher Scientific, Waltham, MA, USA).

Triple FISH was performed by a combination of biotin-labeled Cy3 and Cy5 labeled probes.

To visualize MaSat repeat sequences in MaSat-GFP transfected cells, cells were fixed using a gradient fixation protocol described above and FISH was done as described above. Since heating GFP expressing cells to 80°C dramatically reduced GFP fluorescence, cells were stained with a mouse anti-GFP antibody to re-visualize MaSat-GFP. After probe annealing and washing, cells were first incubated with the anti-GFP primary antibody followed by the secondary donkey-anti mouse Alexa488 antibody and Streptavidin Cy5 incubation for 1 h in blocking buffer (1% bovine serum albumin, 0.5% fish skin gelatin and 0.02% Tween-20 in 1× PBS).

All nucleotide and antibody characteristics are summarized in Supplementary Tables S3 and S4, respectively.

Karyotype analysis

To prepare J1 mES cell metaphase spreads, cells were arrested in mitosis by adding 0.02 μg/ml colcemid (Cat. No.: 10 295 892 001, Roche Diagnostics GmbH, Basel, Switzerland) for 1.5 h at 37°C. The supernatant and harvested cells were pelleted by centrifugation for 5 min at 300 × g, cells were resuspended in 10 ml pre-warmed hypotonic solution (0.075 M KCl) and incubated for 6 min at 37°C. After centrifugation for 5 min at 300 × g, cells were fixed by dropwise addition of fixative solution (3:1 methanol:acetic acid) and incubation for 45 min on ice. Etched microscopy slides were prepared by submerging the slides for 15–20 min in etching solution (0.1 N HCl in 95% ethanol) followed by cleaning steps in 95% EtOH and ddH2O (3 times each). Finally, spreads were generated by dropping fixed cells onto etched slides and air-drying. Individual metaphase spreads were imaged by phase-contrast microscopy and analyzed manually.

Doubling time and S-phase duration

For growth curve analysis, 2 × 10⁶ J1 mES cells were seeded as technical quadruplicates at day 0 and cell numbers were counted with a Neubauer haemocytometer for four consecutive days. Population doubling times were derived with log₂(nx/n₀)/t (h) (nx: cell number at day x, n₀: cell number at day 0).
at day 0, t: hours after seeding). To determine the percentage of cells in every cell cycle and S-phase substage, asynchronously growing J1 cell cultures were pulse labeled with 10 μM EdU for 12 min, fixed and EdU was detected as described. Cells were manually grouped into S-phase substages (stage I to Y), non S-phase or mitosis, and percentages were calculated. S-phase (substage) duration was derived by multiplying the doubling time with the percentage of cells in the respective phase.

**Microscopy**

All characteristics of the microscopy systems, including lasers, filters and objectives used, are summarized in Supplementary Table S5.

Molecular combing samples were imaged using a Zeiss Axiovert 200 widefield microscope.

Confocal z-stacks of live cells were acquired using the Ultra-View VoX spinning disk microscopy system. Time-lapse microscopy was carried out in a closed live-cell microscopy chamber at 37°C, with 5% CO₂ and 60% humidity. mRFP-PCNA and MaSat-GFP double transfected J1 mES cells were imaged every 30 min for 24 h to follow cell cycle progression.

Confocal z-stacks were acquired with a Leica TCS SP5 II confocal laser scanning microscope or the spinning disk microscope.

3D SIM images were acquired with a DeltaVision OMX V3 system (56).

**Image analysis**

Image analysis was done using ImageJ (http://rsb.info.nih.gov/ij/), v1.51s and earlier), Volocity 6.3 (Perkin Elmer), ilastik (57) (https://www.ilastik.org, v1.3.3post3) and Python with the scipy-stack and scikit-image (58). Further analysis was performed using scikit-learn. Missing features were filled with the mean value of that feature in all images. The feature vectors were normalized to zero mean and unit variance and visualized in a 2D embedding via t-distributed stochastic neighbor embedding (t-SNE).

The analysis pipeline is summarized in Supplementary Figure S1 and the Python code for the pipeline is available at https://doi.org/10.25534/tudatalib-220.

**Replication signal and chromocenter colocalization analysis.** To determine the degree of colocalization of replication signals (EdU) and constitutive heterochromatin (chromocenters) in differentiated mES cells, cells were grouped into early, mid and late replicating cells (S₄, S₅ and S₆) according to their EdU pattern. Chromocenters were segmented based on the DAPI signal, EdU signal intensities within the segmented regions were measured and EdU intensities in chromocenters were plotted for S₄, S₅ and S₆ cells.

**Histone modification analysis.** To determine the histone modification accumulation at chromocenters, cells were segmented at single mid planes according to the DAPI channel and DAPI intensities were measured. S-phase cells were identified based on the EdU signal and cells were grouped into G1, S and G2 phases (intensity[DAPI]G1 < intensity[DAPI]S < intensity[DAPI]G2) (20). For subsequent histone modification analysis, only G1 phase cells were considered. Within the DAPI channel, four circular regions of interest (ROI) were drawn inside DAPI intense chromocenters at mid planes, and four ROIs outside chromocenters. Histone modification levels were measured inside the eight ROIs. The analysis pipeline is summarized in Supplementary Figure S2. Mean intensity averages were calculated for the four regions inside chromocenters (chromocenter) and accordingly for regions outside chromocenters (nucleoplasmin). Histone modification accumulation at chromocenters was determined as a ratio of chromocenter/nucleoplasmin.

To determine histone modification changes after HDAC1 targeting to chromocenters, histone acetylation levels were measured in mid focal planes of individual transfected cell nuclei. Background in the histone channel was subtracted and fluorescence intensities were measured. Results are plotted as a ratio to GFP control cells.

**Chromocenter characteristic analysis.** Images of DAPI stained nuclei of (un)differentiated J1 mES cells and primary mouse ear fibroblasts were imported into Volocity 6.3 (Perkin Elmer). Pericentromeric heterochromatin (chromocenters) were segmented based on fluorescence intensity and the total number of chromocenters per cell as well as the volume, the degree of compaction and the shape factor of every chromocenter were calculated.

**Repli-FISH analysis.** To determine the replication timing of specific (sub)chromosomal elements, 3D masks of individual cell nuclei were manually generated based on the confocal PSF were discarded. For each image, a single feature vector consisting of medians and standard deviation of the RFI features (see Supplementary Figure S1 for complete list of analyzed parameters), as well as the number of RFI and the chase duration was created. Further analysis was performed using scikit-learn. Missing features were filled with the mean value of that feature in all images. The feature vectors were normalized to zero mean and unit variance and visualized in a 2D embedding via t-distributed stochastic neighbor embedding (t-SNE).
DAPI counterstaining (single FISH) or the EdU staining (triple FISH). FISH signals were segmented independently after applying a Gaussian filter (sigma = 1) and subtracting background (rolling ball algorithm with radius = 10). Similarly, PCNA images were background corrected and basic PCNA signal from non replicating cells (non S-phase cells) was subtracted. The 3D nucleus mask was subsequently applied to the segmented FISH signals and the generated nuclear FISH ROIs were used to mask the PCNA signals. PCNA intensities within the mask were measured and plotted. The analysis pipeline is summarized in Supplementary Figure S3.

To analyze if the replication timing of telomeres is dependent on their 1D proximity to chromocenters, telomere signals (visualized by Repli-FISH in combination with PCNA) in stage II S-phase cells were segmented and grouped according to their location compared to chromocenters. Telomeres located on the short arm of acrocentric mouse chromosomes are in close 1D proximity of pericentromeric heterochromatin (referred to as telomeres in chromocenters), while telomeres capping the long arm of chromosomes are more distant from major satellite repeats (referred to as telomeres out of chromocenters). PCNA intensities within the segmented telomere signals were measured and plotted.

Replication foci analysis. Quantification of replication foci within individual cell nuclei was mainly performed as described in (28,53). In brief, 3D-SIM images were reconstructed, exported from the DeltaVision software (softWoRx 6.0 Beta 19, Applied Precision) and raw 3D-SIM images were converted to 16-bit images using a custom-written FIJI (59) macro. Individual cell nuclei were segmented using maximum intensity projections of the DAPI signal. Replication signals were segmented by auto-thresholding using the Triangle method. The resulting binary images were used to mask the original replication foci signals of interest and to discriminate them from background (set to ‘0’). These images and the corresponding DAPI images were imported to the image analysis software Volocity 6.3 (Perkin Elmer) and replication foci were quantified for individual nuclei. First, nuclear masks were generated based on the DAPI images and defined as regions of interest (ROIs). Next, 3D-SIM replication foci were detected by intensity excluding only black pixels (i.e. background with intensity ‘0’), touching foci were separated (object size guide = 0 μm²) and signals smaller than 0.0002 μm² were excluded from the final counting as they represented unspecific background signal. Only foci within the nuclear ROI were counted. A detailed analysis pipeline is summarized in Supplementary Figure S4.

Pseudo wide-field (pseudoWF or pWF) replication signals were generated from the same datasets (C2C12 and J1 mES cells labeled with BrdU). Generation of the pseudo wide-field data was described in (60). For correlation analysis, the pseudoWF images were initially processed in ImageJ to match the image dimension of the 3D-SIM data. To achieve similar voxel sizes (40 × 40 × 125 nm), the images were scaled using a bicubic interpolation, doubling the number of pixels in x and y. Next, pseudoWF images were corrected for pixel shifts by translating the image stack ~2 pixels in x and y. For segmentation of the pseudoWF replication signals, the histogram was normalized and a background subtraction was performed using a rolling ball algorithm with radius = 10. Segmentation was performed by auto-thresholding using the Otsu algorithm. 3D-SIM replication signals were processed as described above. Finally, segmented and masked pseudoWF and 3D-SIM image stacks were merged and used for foci counting in Volocity. Detection of pWF RFi was based on intensity as for 3D-SIM images, separation of touching objects was based on object size (object size guide = 0.02 μm²) and signals smaller than 0.02 μm² were excluded. Overlapping signals used for nanoRFI counting within pWF RFi were filtered by an additional compartmentalization step. The analysis pipeline is summarized in Supplementary Figure S5.

DNA fiber analysis. For replication signal analysis from molecular combing experiments, fluorescent DNA fiber tracks were selected according to their pattern. Only lengths of the second pulse (CldU) of progressing forks (CldU track preceded by a clear IdU signal on fibers with a ssDNA signal up- and downstream of the marked tracks) were considered. Replication fork speed (RFS) was calculated as a ratio of the track length (track length × 2000 due to the constant stretching factor resulting in 1 μm ~ 2000 nts) and the time of nucleotide application. Inter-origin distance (IOD) was calculated in kb as the product of the measured track length and the conversion factor of 2 (1 μm ~ 2000 nts or 2 kb).

Bidirectional fork asymmetry was analyzed as the ratio of the long track and the short track and percentage of unidirectional forks was calculated by dividing the number of unidirectional forks by the total number of analyzed forks (uni- and bidirectional forks). A graphical summary of the selection of the fiber tracks and the corresponding calculations are depicted in Figure 7A and Supplementary Figure S6.

Genome-wide replication origin profiling.

The GEO (Gene Expression Omnibus, https://www.ncbi.nlm.nih.gov/geo/) samples GSM3602315, GSM3602316 and GSM3602317 from the dataset GSE126477 (61) and samples GSM2651111 and GSM2651112 from the dataset GSE99740 (62) were used for genome-wide replication origin profiling in mES cells. The samples GSM2651107 and GSM2651108 from the dataset GSE99740 (62) were used for genome-wide replication origin profiling in MEF cells. The above-mentioned datasets correspond to five replicates of origin mapping in mES cells and two replicates in MEF cells realized by sequencing of isolated small nascent DNA strands (SNS-seq). The analysis was performed using peaks reproducibly found in at least two replicates using the multiIntersectBed command in bedtools (63).

The GEO samples GSM3227970, GSM3227971 and GSM3227972 from the dataset GSM3227972 (64) were used for genome-wide replication origin profiling in activated mouse B cells using Okazaki fragment sequencing method (OK-seq). The coordinates of OK-seq replication initiation zones were kindly provided by Andre Nussenzweig and Sridharan Sriram. The mm10 reference genome (http://hgdownload.cse.ucsc.edu/goldenPath/mm10/bigZips/) was
used in all data analysis. The operations on genomic intervals were performed using bedtools (63).

The IODs were calculated between the middle point of each replication origin zone identified and the distances between origins flanking chromosomal regions unmapped in sequencing analyses (centromeres, etc.) were omitted from the plots.

All genome-wide origin mapping datasets and samples are summarized in Supplementary Table S6.

Data visualization and statistical analysis

Data visualization and statistical analysis (independent two-group student’s t-tests and Mann–Whitney–Wilcoxon tests) were performed with RStudio (v1.0.143–v1.1.447, https://rstudio.com/).

Visualization of origin replication profiles was performed with IGV (Integrative Genomics Viewer, version 2.8.6, https://software.broadinstitute.org/software/igv/).

Statistical values (number (#) of cells (N), mean, median, standard deviation (SD), standard error of the mean (SEM), 95% confidence interval (CI) and P-values) are indicated in the plots or summarized in Supplementary Tables.

Boxplots and violin plots represent the median (center line) with the box depicting the 25–75 percentiles and the lines the upper and lower whiskers with 1.5 times the IQD (inter-quartile distance) (Supplementary Figure S7). BarpLOTS show averaged values and error bars the respective standard deviation.

All cells analyzed (N numbers stated in Supplementary Tables) showed the reported behavior of the representative images shown in the respective figures.

RESULTS AND DISCUSSION

Characterization of the spatio-temporal DNA replication patterns in mouse embryonic stem cells reveals differences to somatic cells

Replication patterns are a direct visual representation of the spatial organization and temporal order of DNA replication and, in somatic cells, have been shown to reflect the chromatin organization level (10,15,16). DNA replication timing profiles (RT-profiles) from large cell populations (43,65–68) revealed distinct replication domains (1.5–2.5 Mb), that exhibit sharp boundaries between neighboring domains with different replication timing, alternating along individual chromosomes (43). While RT-profiles can directly be linked to the underlying DNA sequence, they fall short on temporal resolution and do not provide 3D spatial information. Single cell microscopy analysis, however, allows a specific 4D analysis of DNA replication. Importantly, it allows to map replication timing of DNA repeat elements, which are largely not mappable by sequencing-based approaches and constitute a very large portion of mammalian genomes (69). To investigate and compare the spatio-temporal organization of DNA replication (5) of pluripotent cells, we first analyzed S-phase progression in mouse mES cells by live cell imaging experiments. Therefore, we transfected J1 mES cells with plasmids encoding for mRFP-PCNA and a GFP tagged polydactyl zinc finger protein specifically binding to major satellite sequences (MaSat PZF) and imaged the cells every 30 min for 24 h (Figure 1A). To exclude artifacts introduced by transfection and overexpression of fluorescently tagged PCNA, we validated mRFP-PCNA localization during S-phase by immunostaining with a PCNA specific antibody on transfected mES cells (Supplementary Figure S8A). Additionally, we validated binding of the MaSat PZF to major satellite repeats. Due to its high mobility and fast binding kinetics, MaSat PZF is not fixable with standard formaldehyde or methanol fixation protocols. We, therefore, established a gradient formaldehyde fixation protocol with simultaneous permeabilization, and performed fluorescence in situ hybridization (FISH) with a probe specifically binding to MaSat repeats. MaSat-GFP colocalized with the major satellite probe signal, as well as with DAPI intense nuclear regions (Supplementary Figure S8B). The live cell microscopy approach provided a detailed spatio-temporal analysis of S-phase progression in vivo and revealed visually distinguishable spatial replication patterns in mouse J1 mES cells (Figure 1A, Supplementary Figure S8C, Movies 1 and 2). At the beginning of S-phase, replication foci distributed homogeneously in the nucleus interior (stage I), possibly reflecting duplication of the euchromatic portion of the genome, as seen in somatic cells. Next, and differing from somatic cells, MaSat PZF-labeled and condensed clusters of pericentromeric heterochromatin (chromocenters, Figure 1B) were replicated (stage II). Although this observation might be unexpected in view of the late replication timing of heterochromatin in somatic cells, it has been previously shown that in Drosophila, satellite sequences became increasingly heterochromatic and late replicating only with successive differentiation at later developmental cycles (70).

After pericentromeric heterochromatin replication, duplication of chromatin located at the nuclear and nucleolar borders was observed in mES cell (stage III), which, in somatic cells, reflects duplication of facultative heterochromatin. Next, the cells displayed a pattern with a decreased number of foci which however increased in size, suggesting clustering of the underlying chromatin fiber. Replication signals were mostly, but not exclusively, located at the nuclear periphery (stage IV). The end of S-phase was marked by a strong accumulation of replication signals within one particular region of the mES cell nucleus (stage IVa). Additionally, we measured the duration of the individual S-phase substages from the live cell microscopy. While early and mid S-phase (stage I and II) lasted over 3.5 and 4.5 h, respectively, the subsequent phases were relatively short, with average durations of ~1 h each (stage III, IV and IV?, Supplementary Figure S8D and Supplementary Table S7).

Next, we validated the observed S-phase progression in mES cells by pulse-chase experiments. Asynchronously growing mouse J1 mES cells were pulse labeled for 12 min with the nucleotide analog 5-ethyl-2′-deoxyuridine (EdU), washed to remove nucleotide excess, chased with thymidine for different periods of time and fixed. Subsequently, replication foci marked by the incorporated EdU and the replisome component PCNA were (immuno)fluorescently detected (Figure 1C and Supplemen-
Figure 1. DNA replication dynamics in mouse embryonic stem cells. (A) Experimental setup of a live cell experiment to determine the in vivo spatio-temporal progression of DNA replication in J1 mES cells. Cells were transfected with plasmids encoding mRFP-PCNA (magenta) and GFP-tagged...
and pericentromeric heterochromatin (chromocenters), respectively. Imaging was performed for 24 h with 30 min intervals. Representative spinning disk confocal images of G1 to S-phase, S-phase substages (I–IV?) and S-phase to G2 progression are shown. The arrowheads in the IV? stage were pulse labeled with the nucleotide analog EdU, followed by various thymidine chase periods (white arrows) and fixation. EdU, i.e. nascent DNA pulse-chase experiment to determine the spatio-temporal progression of DNA replication in mouse J1 ES cells. Asynchronously growing mES cell cultures were pulse labeled with the nucleotide analog EdU, followed by various thymidine chase periods (white arrows) and fixation. EdU, i.e. nascent DNA replication was characterized by the combination of a significant increase in the distance of the RFi from the nuclear border (Figure 1E and Supplementary Figure S12) and a decrease in RFi solidity (‘rougher’). In contrast, stage II was marked by an increase in RFi numbers with a concomitant increase in DAPI intensity. This is in agreement with our findings that DAPI intense nuclear regions, i.e. chromocenters, are replicated during this stage (Figure 1A–D). Moreover, we determined specific characteristic features for stage IV. At the end of S-phase, the amount of RFi decreased dramatically, whereas solidity, i.e. smoothness, increased. As RFi volumes as well as other features in stages III and IV showed no significant differences, we additionally calculated the percentage of the nuclear periphery covered by replication foci in these two stages. The size of the mask used to segment the nuclear periphery was set to the diameter of the RFi located at the nuclear border in stage III (Figure 9C). As in the live-cell data, replication of the large heterochromatin clusters (stage II), colocalizing with DAPI intense nuclear regions (Figure 1D), took place after the early S-phase stage I pattern and was followed by the nucleolar periphery stage III replication pattern. All other features described in the live cell experiments were also reproduced with the pulse-chase approach in fixed cells.

Since mouse ES cells grow in very specific microenvironments in cell culture, which include the presence of leukemia inhibitory factor (LIF) and two inhibitors (2i, PD032591 and CHIR99021) to preserve pluripotency and self-renewal capacities, as well as form 3D colonies, we tested the influence of this stem cell specific microenvironment on the temporal organization of DNA replication. S-phase progression from stage I to stage II was observed for single mES cells (Supplementary Figure S10A) and in cells grown in the absence of the 2i (Supplementary Figure S10B), similar to cells grown in 3D colonies in the presence of 2i and LIF. Additionally, we analyzed the replication foci pattern distribution over time via the above mentioned pulse-chase experiments in mouse E14 mES cells, and found similar spatio-temporal progression as observed for J1 cells (Supplementary Figure S11) indicating a conservation of S-phase characteristics for mouse pluripotent cells.

In summary, the general characterization of the spatial distribution of replication signals during S-phase progression in mouse embryonic stem cells by pulse-chase and live cell experiments led to the identification and temporal classification of a sequence of replication patterns, which differ from somatic cells (Figure 1E).

Quantitative features of mouse embryonic stem cell replication foci patterns

To characterize the different replication patterns observed in live cell and pulse chase experiments (Figure 1E), we determined quantitative features of the underlying replication foci (RFi) within the different S-phase substages (I–IV?). EdU labeled cells were classified according to their S-phase pattern, replication signals were segmented, separated using a watershed algorithm and location, shape and intensity features were determined (Figure 1E and Supplementary Figure S12). In a 2D embedding via t-distributed stochastic neighbor embedding (t-SNE) the RFi features did not form clearly separated clusters, but temporally adjacent stages lied next to each other in the embedding, hinting at a continuum in feature space from the beginning to the end of replication (Supplementary Figure S13). Stage I of mES cell S-phase was characterized by the combination of a significant increase in the distance of the RFi from the nuclear border (Figure 1E and Supplementary Figure S12) and a decrease in RFi solidity (‘rougher’). In contrast, stage II was marked by an increase in RFi numbers with a concomitant increase in DAPI intensity. This is in agreement with our findings that DAPI intense nuclear regions, i.e. chromocenters, are replicated during this stage (Figure 1A–D). Moreover, we determined specific characteristic features for stage IV. At the end of S-phase, the amount of RFi decreased dramatically, whereas solidity, i.e. smoothness, increased. As RFi volumes as well as other features in stages III and IV showed no significant differences, we additionally calculated the percentage of the nuclear periphery covered by replication foci in these two stages. The size of the mask used to segment the nuclear periphery was set to the diameter of the RFi located at the nuclear border in stage III (Figure 6A–D).
Constitutive heterochromatin shifts its replication timing during loss of pluripotency

In somatic cells, S-phase progression follows chromatin compaction and is commonly subdivided into early (S_e), mid (S_m), and late (S_l) when euchromatin, facultative and constitutive heterochromatin, respectively, are replicated (1,7,14). Since we observed replication of mES cell chromocenters within the first half of S-phase, we aimed to clarify if and when during mES cell differentiation, replication timing of chromocenters switches to late replication. Therefore, we differentiated mES cells in the absence of 2i and LIF and in the presence of retinoic acid (RA) and performed pulse-chase labeling from day 3 to day 7 of differentiation (Figure 2A). During differentiation, mES cell morphology changed from round and compact 3D colonies (day 0) to more flat and spread out cells growing in a monolayer (day 7, Figure 2B). Concomitantly, levels of the pluripotency markers Oct4 and Sox2 decreased dramatically already after 3 days of differentiation and were almost undetectable after day 7 of differentiation (Figure 2C and Supplementary Table S8). All together, these results indicated loss of the stem cell phenotype and pluripotency markers that are associated with exit from pluripotency and cellular differentiation.

At day 7 of differentiation, the beginning of S-phase was marked by very few replication foci (very early S-phase, S_ve), followed by a homogeneous distribution of replication foci throughout the nucleus (S_e, Figure 2D). Interestingly, and in contrast to undifferentiated mES cells (Figure 1), replication signals were next observed at the nucleolar periphery (S_n). Importantly, replication of chromocenters took place at the end of S-phase (S_l) and was followed by transition to G2 phase. Colocalization analyses between DAPI intense nuclear regions and EdU signals showed increased overlaps of the two signals in cells showing a late S-phase pattern, further confirming the switch to late replicating chromocenters in differentiated mES cells (Figure 2E and Supplementary Table S8). In summary, the observed spatio-temporal order of replication pattern in differentiated mES cells reflects the subdivision into S_e, S_m and S_l known from somatic cells (Figure 2F).

Replication timing of constitutive heterochromatin depends on histone acetylation levels

Chromocenters are marked by the trimethylation of histone H3 at lysine 9 (H3K9me3, [47]), by histone hypoacetylation (71), exhibit increased levels of DNA methylation (72) and are bound by specific heterochromatin proteins (73). Previous studies showed that cell types of a different origin or developmental status have a different organization of pericentromeric heterochromatin (74–76). In view of this and since a more open chromatin state was proposed to facilitate early replication onset, we characterized pericentromeric heterochromatin clusters in DAPI stained mES cells and compared them to chromocenters of differentiated mES cells and primary mouse fibroblasts (Supplementary Figure S14A and Supplementary Table S9). Average numbers of chromocenters doubled over cell differentiation (Supplementary Figure S14B and Supplementary Table S9), reflecting differences in clustering of the pericentromeric regions from multiple chromosomes. Cooperatively with the increase in chromocenter numbers, we observed a decrease in the volume of individual chromocenters in differentiated cells (Supplementary Figure S14C and Supplementary Table S9). In line with this, analysis of the compaction state of the chromocenter clusters in pluripotent cells showed a more decompacted chromatin (Supplementary Figure S14D and Supplementary Table S9) and a more irregular shape (Supplementary Figure S14E and Supplementary Table S9). Accordingly, super-resolved chromatin mobility assays demonstrated a more dynamic chromatin and less defined domain structures in mES cells (77). In addition, chromatin associated proteins were found to be more mobile in pluripotent cells (78,79). It is considered that such an open conformation represents a necessary prerequisite of pluripotent cells to remain responsive to the changes that occur during differentiation (80). Additionally, the differences in clustering of chromocenters reflect the chromatin reorganization that occurs during differentiation and development (73,81). The observed differences in heterochromatin morphology, volume, clustering and compaction may provide a mechanistic basis for the observed changes in the DNA replication program of mES cells. However, a general decompaction at the scale measured via DAPI staining of DNA may not be sufficient to promote early replication of pericentromeric heterochromatin. Additionally, maintenance of late replication timing of pericentromeric heterochromatin in somatic cells was shown to depend on histone hypoacetylation (32). We, therefore, compared histone acetylation levels of chromocenters in (un)differentiated and primary mouse fibroblasts (Figure 2G) and found higher H3K9ac and H4K8ac accumulation at chromocenters in undifferentiated mES cells (Figure 2H and Supplementary Table S8). Heterochromatin acetylation levels decreased significantly during differentiation, concomitantly with the switch of replication timing of pericentromeric heterochromatin from relatively early (stage II) to late replication (S_l). Since H3K9ac and H3K9m3, a marker for constitutive heterochromatin, are found in a mutually exclusive way in cells, we also analyzed accumulation of the latter at chromocenters. In line with the increased acetylation levels, we found less H3K9m3 accumulation in pluripotent stem cells and an increase in H3 lysine 9 trimethylation in differentiated cells (Figure 2H and Supplementary Table S8). This result is in line with genome wide studies as well as single cell microscopy analysis showing that histone acetylation is an important regulator of the replication timing of DNA. While genomic loci with increased histone acetylation levels and high accessibility tend to replicate early during S-phase, loss of histone acetylation leads to replication timing switch to late S-phase (32–34,82–89). Taken together, mid S-phase replication of pericentromeric
Figure 2. DNA replication dynamics in differentiated mouse embryonic stem cells. (A) Experimental setup of pulse-chase experiments in differentiated mouse J1 ES cells. Naïve pluripotent mES cells were cultured in 2i (two inhibitors (PD032591 and CHIR99021)) and LIF (leukemia inhibitory factor).
heterochromatin in pluripotent stem cells is changed to late replication in differentiated mES cells and this switch in replication timing is likely dependent on histone hypoacetylation and chromatin compaction occurring during cell differentiation.

To validate the causality between the observed histone hyperacetylation and early/mid replication of pericentric heterochromatin in mES cells, we tagged a GFP taggeed histone deacetylase to chromocenters in mES cells (90). Specific chromocentric targeting was achieved via co-transfection of GFP tagged HDAC1 and a GFP binding protein (GBP) tagged MaSat polydactyl zinc finger (PZF) protein (GBP-MaSat). MaSat PZF specifically binds to major satellite repeat DNA (chromocenters) and its GBP domain interacts with GFP-HDAC1, thereby recruiting the deacetylase to chromocenters (Figure 3A). As a control, we targeted GFP to chromocenters. With this setup, we first analyzed histone acetylation levels in transfected cells, and found decreased H4K5ac and H4K8ac levels in HDAC1 targeted cells compared to control GFP cells (Figure 3B and Supplementary Table S8). To analyze spatio-temporal S-phase progression in transfected cells with altered chromocentric histone acetylation levels, we performed pulse chase experiments. Therefore, 24 h after double transfection, cells were labeled with EdU, chased for 2 h and fixed. EdU and PCNA were (immuno)fluorescently detected and DNA replication progression was investigated by pattern order analysis as before. In GFP control targeted cells, we observed spatio-temporal DNA replication progression as previously described. Pericentric heterochromatin was replicated before perinucleolar chromatin and finally replication signals were observed as bigger replication foci throughout the nucleus (stage II–stage III–stage IV). In HDAC1 targeted cells, however, we observed two populations of cells. First, we found cells following the classical mES cell replication progression where S-phase moves from chromocenters to the perinucleolar border. Second, cells showed replication of the perinucleolar chromatin followed by replication signals in normally earlier replicating chromocenters (stage ‘III’ to stage ‘II’). This indicates an at least partial delayed chromocenter replication upon histone acetylation level decrease (Figure 3C-D and Supplementary Table S8). Quantitative analysis revealed almost equal distributions between the two substage orders in HDAC1 targeted cells, while control cells only showed stage II to stage III transitions (Figure 3D and Supplementary Table S8). Interestingly, after HDAC1 targeting we observed massive rearrangements of pericentric heterochromatin. GFP control cells exhibited few but large chromocenters, while 24 h of histone deacetylase targeting resulted in an increased number of constitutive heterochromatin clusters with decreased size. Analyzing chromocenter characteristics, we measured similar volumes and shape factors for control cells than in untransfected mES cells (Figure 3D-E, Supplementary Figure S14C, S14E and Supplementary Tables S8 and S9). HDAC1 targeted cells were sub-divided according to their S-phase progression pattern (II to III or ‘III’ to ‘II’). We detected significant changes in chromocenter volumes in stage ‘III’ to ‘II’ cells compared to control and stage II to III cells. Additionally, shape factors were also significantly different in targeted cells showing a replication pattern switch (Figure 3E-F and Supplementary Table S8). In conclusion, we show that a targeted histone deacetylation of mES chromocenters leads to a switch in replication timing of pericentric heterochromatin to later in S-phase, mimicking our findings in differentiated mES cells (Figure 2D).

**Replication timing of (sub-)chromosomal elements in mouse embryonic stem cells**

In human and mouse genomes, only minor parts (1.2–1.4%, respectively (91,92)) are protein-coding sequences, while the major portion is composed of non-coding DNA, including interspersed and tandem repeat sequences. There is growing evidence that the latter is more than ‘junk’ DNA, since it is thought to be involved in the establishment of distinct euchromatic and heterochromatic compartments (93–95). Additionally, genome function might not only be influenced by epigenetic factors, but also by the spatial organization of the genome within the cell nucleus (96). Hence, we analyzed the nuclear distribution and the replication timing of several sub-chromosomal tandem repeat elements in mouse ES cells. Due to their repetitive nature, repeat elements are normally under-represented in genome-wide sequencing studies. We, therefore, opted for a single cell microscopic approach, where we combined DNA replication visualization and marking of three major chromosomal tandem repeats containing medium. On day 0 of the differentiation, cells were seeded in 2i and LIF deficient medium containing retinoic acid. Cells were pulse labeled with EdU, chased with thymidine for 2 h and fixed at day 0 and from day 3 to day 7 of the differentiation. (B) Overlay of phase contrast (Ph) and DAPI channels, showing changes in cellular morphology during mES cell differentiation. (C) Immunofluorescent detection of the pluripotency markers Oct3/4 and Sox2 in (un)differentiated mES cells. Representative spinning disk confocal images of *in situ* stainings were imaged and the mean value of the fluorescence signal was plotted as a ratio to the undifferentiated (day 0) cells. (D) Representative spinning disk confocal images of pulse chased mES cells revealed replication timing switch to late replicating chromocenters at day 7 of differentiation. Very early (S0) to early S-phase (S1), early to mid (S2), mid to late (S3) and late S-phase to G2 transitions are shown. (E) To analyze the replication timing switch of chromocenters in differentiated mES cells, the sum value of EdU fluorescence signal within chromocenters (masked according to DAPI channel) were measured in spinning disk confocal images of cells (from D) within early, mid and late S-phase for the EdU pulse. An increase in signal overlap of chromocenters and replication signal is observed during late S-phase in differentiated mES cells. (F) Schematic summary and corresponding confocal images of the three main replication patterns observed in differentiated mES cells. Replication signals are shown in cyan, pericentric heterochromatin in green (scheme) and replicating chromocenters (late) are marked in dark cyan. (G–H) Experimental setup for the analysis of histone modification accumulation at pericentric heterochromatin. (Un)differentiated mES cells and primary mouse ear fibroblasts were pulsed with EdU to identify S-phase cells and histone modifications were immunofluorescently detected. Regions of interest (ROI) were manually drawn in G1 phase cells and histone modification levels were measured. Shown are the accumulations of H4K5ac, H3K9ac and H3K9me3 at chromocenters (ratio of mean histone modification values at chromocenters and mean histone modification values in the nucleoplasm ± StDev). Scale bars = 5 μm. *P < 0.05. All experiments were done in at least two independent biological replicates. All boxes and whiskers represent 25–75 percentiles and 1.5 times the IQD (inter-quartile distance), respectively and the center line depicts the median (Supplementary Figure S7). Detailed statistics are summarized in Supplementary Table S8. Dotted lines represent cell contours.
**Figure 3.** HDAC1 deacetylase targeting to chromocenters in mouse embryonic stem cells. (A) Schematic representation of the targeting strategy to recruit HDAC1 to chromocenters. In a targeted state, the fusion protein composed of the major satellite binding MaSat PZF (MaSat) and GFP binding protein
To analyze the replication timing of the repeat elements, we quantified the overlap of the replisome factor PCNA or nascent DNA labeled by EdU with individually segmented repeat sequence specific FISH signals within 3D mES cell interphase nuclei. The specificity of the FISH probes for (peri)centromeric DNA (major and minor satellites, respectively) and telomeres was validated by their location on mitotic chromosomes (Supplementary Figure S15B and (55)). Major satellite pericentromeric repeats were visualized as large clusters of DNA, co-localizing with chromocenters, marked by bright DAPI counterstaining, and mainly associated with the nuclear periphery and nucleoli in the 3D nucleus (Supplementary Figures S16A, S17A and Supplementary Table S10). Strongest overlap with PCNA or EdU was observed in S-phase stage II (Figure 4B, Supplementary Figures S16A, S15A, S18A–B and Supplementary Table S10) in line with our results above from in vivo and pulse-chase experiments (Figure 1). Minor satellite centromeric repeat signals were seen as small focal structures located in close proximity to chromocenters (Figure 4B, Supplementary Figures S16B, S17B, S18B–C and Supplementary Table S10). Akin to major satellite repeats, centromeric DNA of mES cells was found to also replicate preferentially in early/mid S-phase (stage II). Centromeres of Drosophila as well as yeast, were found to replicate only early in S-phase suggesting that early replication timing is a conserved feature of centromeres (97,98). In mouse fibroblasts, however, centromere replication was also reported to occur throughout S-phase (99,100). Given their physical location along chromosomes and their 3D organization in interphase nuclei (Supplementary Figure S15A and (72)), it is likely that centromeric regions are also less compacted in mES cells so that partial overlap of the replication timing profiles of these two structures can be expected. Furthermore, and as shown in somatic cells (99), centromeric repeats likely replicate just before or after the directly adjacent pericentromeric chromosomal domains. In the case of telomeres, the FISH signals distributed as smaller individual foci throughout the cell nucleus (Figure 4B, Supplementary Figures S16C, S17C, S18A, S18C and Supplementary Table S10). Overlap of replication and telomere signals was observed at all S-phase stages, with an increase during stage II.

Although our previous observations (Figure 1A and C and Supplementary Figure S11) suggest a difference in chromatin clustering in S-phase stage III and IV, we could not identify any specific tandem repeat sequence underlying these stages. Since none of the RFI features quantitatively analyzed (Supplementary Figure S12) showed significant differences between these two stages, we consider this part of S-phase as one substage and will refer to it, hereafter, as stage III.

Since the J1 mES cells were derived from the inner cell mass of a male blastocyst (45), we additionally analyzed the replication timing of the Y chromosome (Supplementary Figure S15C). The strong accumulation of replication signals observed in stage IV of S-phase showed a significant overlap with FISH signals specific for the Y chromosome (Figure 4C, Supplementary Figures S16D, S17D, S18A–C and Supplementary Table S10). We, therefore, consider S-phase stage IV as the male specific S-phase stage where the Y chromosome is replicated and will refer to it, hereafter, as stage Y.

Since we measured an increase in PCNA-telomere signal overlap in S-phase stage II cells, we analyzed if telomere replication timing was dependent on their 1D proximity to pericentromeric heterochromatin, which is replicated during this stage of S-phase. We, therefore, segmented telomeres in stage II S-phase cells, grouped them according to their location with regards to chromocenters and measured PCNA signal intensities within the segmented regions. Telomeres on the short arm of acrocentric chromosomes (telomeres in chromocenters) showed higher PCNA signals in stage II cells than telomeres capping the long chromosomal arms (telomeres out of chromocenters, Figure 4D and Supplementary Table S10). This observation underlines a potential domino-like replication where the activation of origins of replication takes place in a next in-line manner, thereby spreading from the (peri)centromeric repeats towards the telomeres located on the short arm of the chromosome (99). This is in line with earlier studies relating the replication timing of telomeres to nuclear position, with telomeres positioned towards the nuclear interior replicating earlier than the ones associated with the nuclear periphery (101).

In summary, we characterized the replication timing of the three main classes of tandem repeat sequences and of the Y chromosome via a single cell microscopic approach. (Peri)centromeric DNA was mainly replicated during stage II of S-phase, while telomeres were replicated over the complete duration of S-phase. Replication of the Y chromosome marked the end of S-phase and corresponded to the strong accumulation of replication signals in stage Y (Figure 4E).

**Synchronous replication of the Y chromosome marks the end of S-phase in pluripotent and differentiated cells**

The Repli-FISH method allowed us to determine that the prominent structure that is replicated at the end of S-phase in stage Y in male J1 mES cells is the Y chromosome (Figure 4C). In female cells, the inactive X chromosome (Xi) replicates in a highly synchronous manner and, in contrast...
Figure 4. Replication timing of (sub)-chromosomal structures in mouse embryonic stem cells. (A) Schematic representation of a mouse acrocentric chromosome. Centromeric satellite regions (MiSat) and flanking pericentromeric DNA (MaSat) are depicted in magenta and cyan, respectively and telomeres...
to the active homologue, within a short time interval during early-mid S-phase (31). Similarly, we did not detect any major replication signal at the Y chromosome in any of the other four S-phase stages and, therefore, conclude that the Y chromosome is synchronously replicated within this short period of S-phase stage Y (Supplementary Figure S8D). To further determine if this en bloc replication of the Y chromosome at the end of S-phase is a characteristic of pluripotent mES cells or a general feature of male cells, we analyzed the PCNA and Y chromosome hybridization signal overlap in replicating male mouse embryonic fibroblasts (MEF W8). In addition to the three well-characterized S-phase patterns known from somatic cells (S_0, S_m and S_i), MEF cells showed a fourth pattern with a clear accumulation of replication sites at the Y chromosome (Supplementary Figure S19A and Supplementary Table S10). Pulse chase experiments in differentiated mES cells and mouse embryonic fibroblasts showed a similar pattern after chromocenter replication during late S-phase (S_i) and before transition to G2 phase (Supplementary Figure S19B). The Y chromosome of male cells, one of the smallest chromosomes in mice (~92 Mb), is mostly studied in the context of evolution, clinics and forensics (102) and mainly believed to consist of non-functional DNA (103). At the genomic level, the Y chromosome is marked by a very low gene density (1.7 genes/Mb for mice, (74,104,105)) of which only a fraction appears to be potentially protein coding in humans and that are mostly required for testis development and sex determination, or have a X encoded paralog (105,106). Additionally, the Y chromosome is composed of large heterochromatic DNA blocks (107,108). Therefore, gene expression and transcriptional activity on the Y chromosome are low and a connection between low gene density and transcriptional activity could explain the late replication timing of the male sex chromosome. Accordingly, a correlation between gene expression and replication timing was demonstrated in Drosophila (109) and, similarly, between replication timing, GC content, gene density and transcriptional activity in human cells (68,110–112). Besides this, the Y chromosome is frequently lost in most male cell lines during prolonged cell culture and, thus, neglected in most studies. Our microscopic data provide evidence for a synchronous replication of the Y chromosome marking the end of S-phase independently of the pluripotency state as a general characteristic of mouse male cells. Interestingly, mid S-phase replication of the silenced copy of the X chromosome in somatic female cells, also occurs in a synchronous manner (31), highlighting a common replication mode for transcriptionally inactive chromosomes. This replication mechanism bears resemblance to observations in early Drosophila and Xenopus embryos, where genome duplication is performed in extraordinarily short time frames and in the complete absence of transcription (35,113–116).

Cell cycle and S-phase stage kinetics in mouse embryonic stem cells

Embryonic stem cells have the unique characteristics to replicate indefinitely in cell culture while maintaining their self-renewal capacity and to differentiate into cells of all three germ layers. Their cell cycle also differs significantly from somatic cell types (117) and upon differentiation, cell cycle dynamics undergo massive reorganization (118–120). To study DNA replication kinetics in mouse J1 ES cells, we analyzed total S-phase and S-phase substage lengths, as well as the population doubling time in asynchronously growing J1 mES cells. Cell cycle distribution was analyzed by counting S-phase and non-S-phase cells (G1, G2 or mitotic cells) in EdU pulsed cell populations. On average, around 77% of J1 mES cells were in S-phase at any given time, while 23% were not actively replicating DNA (Figure 5A and Supplementary Table S11). Furthermore, around 31% of S-phase cells were in stage II, replicating pericentromeric heterochromatin, while 25% showed the stage I pattern. The other stages were represented by 20% of the cells. Cell proliferation rates were calculated over five consecutive days and J1 mES cells exhibited a doubling time of around 14 h (Figure 5B), which is in agreement with doubling times measured for other mouse ES cell lines (121). Together with the percentage of cells in S-phase (Figure 5A and Supplementary Table S11), an average S-phase duration of almost 11 h was calculated (Figure 5B). Similarly, S-phase substage durations were derived (Figure 5C). During almost two-thirds of S-phase length, mES cells were present in stage I or II, replicating euchromatic and constitutive heterochromatin. Stage III and Y accounted for only 1/3 of S-phase length. These results are comparable to the S-phase substage durations we measured via live cell microscopy (Supplementary Figure S8D). All in all, J1 mES cells exhibit a similar S-phase duration to somatic cells, however, their doubling time is significantly shorter (28,120). This observation is in line with previous reports that stem cells have shorter gap phases and are devoid of a G1-S transition regulation (118). Strikingly, although mES cells exhibit a different temporal organization of DNA replication, around 72% of S-phase...
are necessary to replicate active euchromatic chromatin and silenced constitutive heterochromatin (stage I and II), which is similar to the time mouse myoblasts and embryonic fibroblasts spend in S<sub>c</sub> and S<sub>t</sub> (20).

**Superresolved replication nanofoci in mouse embryonic stem cells are activated in spatial clusters similar to somatic cells in number but larger in volume**

Advanced optical microscopy techniques allow imaging beyond the resolution limit inherent to light microscopy. By using multicolor 3D structured illumination microscopy (3D-SIM), it was recently shown that individual replication foci are resolved down to single replicons and, to some extent, even to individual replication forks (28). Chromatin organization and chromosomal interactions are known to change during embryonic stem cell differentiation (122). Moreover, differences in the organization of the underlying chromatin fiber, e.g. a more open chromatin conformation, may have an impact on the organization and activation of replication origins, and, in turn, on the regulation of replication timing of different chromatin classes. We therefore analyzed replication microfoci at the different S-phase substages in mouse ES and C2C12 cells imaged with 3D-SIM (nano replication foci or nanoRFi). To quantify the number of super-resolved nanoRFi, mES cells were labeled with 5-bromo-2′-deoxyuridine (BrdU), the nucleotide analog was immunofluorescently detected and S-phase cells were imaged. Replication foci were thresholded, masked and counted as described (53). Comparable numbers of nano replication foci for cells from the first three S-phase substages were obtained, with an average 3320 ± 60 (mean ± SEM) nanoRFi at any given time during S-phase (Figure 6A, B and Supplementary Table S12). Since the number of nano replication foci dropped dramatically at the end of S-phase (stage Y: 1881 ± 214), we excluded this stage from all subsequent calculations. A similar trend was found in the number of RFi measured from confocal microscopy images (Supplementary Figure S12). NanoRFi measurements in somatic cells revealed a decreased number of super-resolved foci in late S-phase cells, when highly compacted constitutive heterochromatin is replicated (28). Interestingly, we detected comparable numbers of nanoRFi in mES stage II S-phase cells and all other S-phase stages. This discrepancy could be explained by the more decompacted heterochromatin in mES cells (Supplementary Figure S14), facilitating individual foci segmentation. Additionally, this result supports the idea that differences in chromatin organization influence DNA replication (78,79,123).

Since origins of replication are proposed to be located at loop anchors (26) and based on the hypothesis that a different chromatin compaction and (loop) organization in mES cells could result in a spatially different organization of nano replication foci and replicons, we compared the numbers of nanoRFi in a given volume within the cell nucleus of mouse myoblast and embryonic stem cells. The 3D-SIM system simultaneously allows the generation of reconstructed super-resolved 3D image sets and the corresponding (pseudo) wide-field (pWF) images (Figure 6C). This allowed us a direct comparison of the total number of RFi per cell from different imaging resolution conditions from the same cells. We, therefore, segmented 3D-SIM nanoRFi and pWF RFi from early and stage I C2C12 and mES cells, respectively, and calculated the population ratio of RFi. The two cell types showed a similar ratio indicating that every RFi imaged at conventional light microscopy resolution corresponds on average to 5.9 and 6.5 super-resolved nanoRFi for C2C12 and mES cells, respectively (Figure 6D and Supplementary Table S12). In addition to the ratiometric approach, we correllatively analyzed the connection of pWF and nanoRFi by determining the number of super-resolved RFi per underlying pWF focus in both cell types. Hence, we first aimed to determine the amount of clustered (> 1 nanoRFi per pWF) versus single (exactly 1 nanoRFi per pWF) nanoRFi within the given volume of the pseudo-widefield focus. Interestingly, in both cell lines, around 72–73% of the nanoRFi formed clusters, while 26–27% of the pWF contained only one nanoRFi. While the above mentioned ratiometric approach includes all detected and segmented pWF, independent of the number of underlying nanoRFi, the correlative analysis takes into consideration only pWF foci containing more than one nanoRFi (clustered nanoRFi). These pWF replication foci comprised clusters of an average 3.82 and 4.02 nanoRFi for C2C12 and mES cells, respectively (Figure 6D and Supplementary Table S12). Notably, stem cell pWF RFi are significantly
Figure 6. 3D quantification and analysis of replication foci throughout S-phase in mouse embryonic stem cells. (A) Mid sections and maximum intensity z-projections (z-max) of 3D structured illumination microscopy (3D-SIM) images of mouse ES cells representative of the first three S-phase patterns (I–III).
larger than myoblast pWF foci while no difference in size of nanoRFi could be detected, suggesting that they correspond to conserved (elementary) structural units of the mammalian genome (28) (Figure 6E and F and Supplementary Table S12). In summary, the observed difference of mES cell replicons from those of mouse myoblast cells, suggests that the underlying chromatin and loop organization is different in mES cells (122,124) and that this difference is reflected in the organization and dynamics of DNA replication (78,79,123). Chromatin loop structures are considered distinct units in the complex hierarchy of genome organization within the cell nucleus. At this level, individual loops may harbor the DNA elements that act as templates or regulators in different molecular processes (reviewed in (27)). The most prominent examples are enhancer elements and promoters of genes that coordinate and regulate transcription via long ranging cis-interactions (94,125,126). Notably, in somatic cells, measured sizes for chromatim loops, replication forks and also nano-repair foci are highly consistent and rely on the same structural DNA unit of about 90 kb (28,60,127). Coherently, a replicon consisting of bidirectional replication forks, duplicates a DNA segment the size of a pair of loops, i.e. around 180 kb (28). Thus, differences in loop conformation and (local) chromatin density are potent features that can modulate interactions between genetic elements that are required for DNA-dependent metabolic processes such as DNA replication. In this regard, it is appealing to propose that if replication origins are defined by loop anchoring sites, then organization of replicons will be directly linked to loop structures.

Molecular characteristics of the replicon in mouse embryonic stem cells reveal increased numbers of activated origin and unidirectional forks

Complete genome duplication once per cell cycle and in the restricted time frame of S-phase depends on two determinants: (i) the number and distribution of initiation sites (i.e. replication origins) along the genome (inter-origin distance) and (ii) the processivity rate (nucleotides/time) of replication forks (replication fork speed) emanating from these sites. With regard to the differences in the spatio-temporal replication dynamics of mouse ES cells described above and in view of the highly dynamic spacing of adjacent origins within replicon clusters in Xenopus and Drosophila development (36,37,113), we aimed to clarify if mES cells exhibit further replication related differences/adaptations compared to somatic cells. To analyze the molecular characteristics of replicons in mES cells, i.e. the replication fork (elongation) speed (RFS) and the inter-origin distance (IOD), we consecutively labeled asynchronous J1 mES cell populations with two halogenated thymidine analogs, IdU and CldU and performed molecular combing assays with isolated high molecular weight DNA that led to uniformly stretched DNA fibres (1 μm ~ 2 kb, Figure 7A). The replication fork speed obtained in mES cells of 1.67 ± 0.02 kb/min (mean ± SEM, Figure 7B) is within the range of fork rates measured by the same single molecule DNA fiber analysis for other cell lines (28,128). This suggests that replication fork speeds are similar between pluripotent and somatic cells. On the other hand, the average inter origin distance of ~90 kb (Figure 7C) is smaller in mES cells compared to mouse myoblasts and human cells (28). This result indicates that the organization of replicons or replicon clusters is different between mouse pluripotent and somatic cells. Although the observed differences in IOD lengths between mES and differentiated somatic cells are not as dramatic as those occurring during development of Xenopus embryos, they suggest that the modulation of inter-origin distances, and concomitantly the resulting replicon sizes, represent a mechanism that is similar between the two species and highlights further developmental differences of the replication timing program of murine ES cells. Of note, while the first cell divisions in the Xenopus zygote occur in the absence of DNA transcription, transcription initiation is observed in the pronuclei of the zygote and at the two-cell stage during mouse development (35–37,39,41,129).

To get a deeper insight in the distribution of genome-wide replication initiation events, we compared the results of our microscopic analysis with the available datasets of sequencing-based genome-wide origin mapping in mES cells (61,62), mouse embryonic fibroblast (MEF) cells (62) and activated mouse B cells (64). This reflects the origin distribution in three different stages of differentiation, from stem cells through differentiated but still reprogrammable MEF cells, to a terminally differentiated B cell line. The origin mapping in mES and MEF cells was realized using short-nascent-strand (SNS-seq) isolation and sequencing (130) and origins in B cells were mapped by Okazaki fragment sequencing (OK-seq) (131). The genome-wide origin mapping was realized using asynchronous cell populations that permit cumulative mapping of all replication origins independently of their timing of firing. A total number of 78 258 and 71 257 DNA replication origins were identified in two independent datasets using mES cells (61,62). In MEF, 34 196 DNA replication origins were identified, i.e.,
Figure 7. DNA replication fiber and genome size analysis in mouse embryonic stem cells. (A) Schematic outline of the experimental setup for DNA fiber analysis. mES cells were sequentially labeled with IdU and CldU for 15 min, harvested and embedded in agarose. After a proteinase K digestion step,
two times less origins than in mES cells. The two times lower number of origins led to a two times larger inter-origin distance in MEF cells in comparison to the mES cells (Figure 7D and Supplementary Figure S20). We determined average IODs of 33.6 and 69.93 kb for mES and MEF cells, respectively (Figure 7E and Supplementary Table S13). Interestingly, the IOD calculated for the somatic chromosomes was two times smaller than for the X chromosome (62 in mES and 82 kb in MEF) (Supplementary Figure S21A-C). This suggests a different spatial origin activation on the two parental homologue chromosomes leading to an apparently smaller IOD calculation than the IOD measured for a single stretched DNA molecule in the combing experiments. The decrease in origin number and increase in the IOD became even more prominent in the terminally differentiated B cell line activating around 9000 origins. The SNS-seq and OK-seq differ in the origin-mapping precision, the SNS-seq method offers a very good mapping resolution and identifies all possible initiation sites (ISs). With an average peak size of 0.5 kb in the datasets analyzed (Supplementary Figure S22A and Supplementary Table S13), most of the ISs are situated in close proximity and represent alternative origin firing patterns within a cell population. The OK-seq identifies large initiation zones (IZs) with an average resolution of 22 kb (Supplementary Figure S22A) without distinguishing single initiation sites. To equalize the resolution of the two methods for comparison purposes, all SNS-seq initiation sites were clustered in the distance of the average resolution of OK-seq origin mapping (22 kb). As a result of this operation, all origins found in mES and MEF cells were clustered in 33 765 and 23 862 border IZs, situated at an average distance of 70.8 and 100.2 kb, respectively. In contrast the 9000 IZs identified in the activated B cells were spaced at the distance of 288 kb (Supplementary Figures S20 and S22B). This result suggests a gradual decrease in origin firing and increase in origin spacing during differentiation and supports our finding of smaller inter-origin spacing in mES cells compared to somatic cells obtained from single molecule DNA combing data.

Next, we analyzed the portion of single/unidirectional forks (replication forks without counterpart/opposite direction fork) per total forks present in mES cells and observed that around 13% of all forks migrate away from the origin of replication in only one direction (Figure 7F and Supplementary Figure S6). The presence of unidirectional forks has also been found in sequencing-based genome-wide origin mapping techniques in human cells. In the latter, genome duplication relies on 4.1% to 7.3% of unidirectional forks (131). We obtained similar numbers upon extracting the amount of unidirectional forks from the DNA combing analysis datasets of Chagin et al. (28), where we measured 5.5 ± 1.3% of forks travelling in only one direction from the origin of replication. In addition, we also analyzed the (a)symmetry of bidirectional forks and found that the two forks proceeding in opposite directions from the same origin mostly travel at similar rates (Figure 7G). This suggests that the replication forks of mES cells do not experience a high level of stalling events due to exogenous or endogenous factors, albeit mES cells are transcriptionally hyper-active (132).

In view of the above mentioned essential parameters for genome duplication once every cell cycle, the karyotype and the resulting genome size of a cell line is important for the determination of replicon characteristics. Most established cell lines used for in vivo studies have initially been transformed in order to immortalize them and to revive agarose was digested and high molecular weight naked DNA was stretched on silanized glass coverslips. Nucleotide analogs and single stranded DNA (ssDNA) were immunofluorescently detected. (B–E) The length of fluorescent tracks of the second pulse (CldU) were measured (1 μm ~ 2000 nucleotides, Supplementary Figure S6) and the mean replication fork speed (RFS, (B)), inter-origin distance (IOD, (C)), percentage of unidirectional forks (F) and asymmetry of bidirectional forks (G) were calculated as indicated in (A). Additionally, the percentages of forks within a given range of RFS are indicated in (B). For comparison of the RFS of the ‘left’ and ‘right’ fork of a bidirectional fork, RFS values were plotted in a scatterplot. The solid grey line represents the linear relation x = y and dotted lines represent thresholds allowing for a 35% (± StDev calculated for the asymmetry factor) difference between lengths of the two forks. (D) Visual representation of origin mapping in two arbitrarily selected regions (mouse (Mus musculus, mm10) chromosomes 9 and 11). SNS-seq origin profiles and identified origins in mES and MEF cells are shown. OK-seq origin profiles in activated (act.) B cells, called peaks along with the middle point of each peak are represented. Replication profile scale is indicated in the upper left corner. The comparison between identified and clustered origin peaks is shown in Supplementary Figure S20. (E) IOD distributions based on the genome-wide origin maps in mES cells and mouse embryonic fibroblast (MEF) are shown (SNS-seq). The sequencing datasets used for the analysis include two independent replicates of origin mapping for each condition. (F) Ploidy of J1 mES cells was determined via karyotype analysis of metaphase spreads. For genome size calculation, the sizes of individual mouse chromosomes (19 autosomes + X + Y chromosomes) were retrieved from the Genome Reference Consortium database. Additionally, genome sizes measured by flow cytometry are indicated. Boxplots/violin plots are as in Figure 2 and Supplementary Figure S7. Statistical details are depicted in the plots or summarized in Supplementary Table S13. All experiments were done in at least two independent biological replicates. Black dots within box/violin plots represent mean values. * P < 0.05. Scale bar = 5 μm.

### Table 1. mES cell replicon characteristics

| Experimental data | Mean ± SEM |
|-------------------|------------|
| RFS, 1000 nts per min | 1.67 ± 0.02 |
| IOD, kb | 90 ± 3.6 |
| Genome size (GS), 1000 Mb | 5.19 ± 6.5*** |
| Active RFi at any given point during S-phase | 3.320 ± 0.20 |
| Total S-phase duration, minutes | 654 ± 21 |
| Single forks, % | 12.81 ± 8.6 |

### Calculations

| Calculations | Mean |
|--------------|------|
| Time to replicate the genome with one fork, (GS/RFS), hours | 51 796–64 870 |
| Replication forks active in parallel, (GS/RFS/S-phase duration) | 4 752–5 951 |
| Replicons active in parallel, (active forks/2) | 2 376–2 976 |
| Replicons per RF, (calculated replicons active in parallel/counted RFi) | 0.72–0.9 |
| Calculated % of single forks | 10–28 |

RFS, replication fork speed; nts, nucleotides; IOD, inter-origin distance; GS, genome size (based on published genome data); RF, replication focus; RFi, replication foci; SEM, standard error of the mean; * GS according to mouse reference genome (GRCm38); ** GS according to flow cytometry measurements.
Figure 8. Graphical summary of the cellular and molecular DNA replication characteristics in mouse embryonic stem cells. At the cellular level, DNA replication is visible as distinct replication foci with a dynamic spatio-temporal organization. In mES cells, three different replication patterns are observed.
their replicative potential. Such procedures, however, often introduce undesired genetic aberrations which are known to drastically influence the ploidy of the transformed cell line. Embryonic stem cells, on the other hand, are derived from the inner cell mass (ICM) of the blastocyst and are, by nature, capable of sustaining their proliferative state in culture. Moreover, they have been described to maintain a stable diploid karyotype (133). Nonetheless, we performed karyotype analysis of J1 embryonic stem cells from metaphase chromosome preparations and calculated the approximate genome size taking advantage of published genome data available from the Genome Reference Consortium (92) for haploid mouse genomes. Manual counting of >100 metaphase spreads confirmed a diploid karyotype of the mouse J1 cell line, consisting of 40 acrocentric chromosomes (Figure 7H and Supplementary Table S13). To derive the total genome size, we used the mouse genome assembly GRCm38.p6 mm10 that provides sequencing derived sizes for each chromosome of a haploid mouse genome. Based on this, we calculated a male diploid genome size for mES cells of 5.182 Gb (Figure 7H). Since genome-wide sequencing approaches are affected by unmappable repetitive sequences, this likely is an underestimate of the actual genome size. Indeed, using data from flow cytometry based approaches we obtained diploid mouse genome sizes of 6.03–6.5 Gb (134,135).

Model for genome replication in embryonic stem versus somatic cells

Using the above mentioned characteristics of mES cell DNA replication and molecular parameters of the associated replicons (i.e. genome size, S-phase duration, number of nanoRFi, IOD and RFS, see Table 1), we analyzed the relationship between replicons and replication foci in mES. The total number of replicons, reflecting the number of origins activated during S-phase, is given by the genome size divided by the average inter origin distance obtained from DNA fiber experiments. This calculation resulted in a total of 57 700–72 300 origins activated during the S-phase of mES cells, depending on how the genome size was estimated. These values are comparable to the number of replication origins obtained by genome-wide origin mapping techniques (see above and (61,62)). Since IOD measurements may be more affected by the sample quality and the length of DNA fibers obtained during the DNA isolation and combing procedure (128), we additionally focused on RFS to determine the number of active replication foci at any given time and to compare it with the actual numbers of foci active in parallel obtained from our 3D-SIM data.

The genome size divided by the average speed of a replication fork represents the time required to synthesize the entire genome if only one fork would be active for the entire length of S-phase. Dividing this time by the actual measured S-phase duration, thus effectively represents the number of all active replication forks required at any given time during S-phase. These calculations showed that ~4750–5950 forks or half as many bidirectional replicons (~2380–2980) are required to act in parallel in mES cells (Table 1). Comparing the nanoRFi active in parallel counted in 3D-SIM images to the theoretically ‘needed’ RFi active at any given time during S-phase, resulted in a ratio of 0.72–0.9 (2376/3320–2976/3320 RFi), indicating that mES cells activate more replicons than ‘needed’ for genome duplication within the timeframe of S-phase.

The difference in predicted and measured active replication foci can be explained by a higher frequency of nanoRFi that contain single replication forks and could be resolved by 3D-SIM. The latter would involve the presence of 10–28% of unidirectional forks in mES cells to make up for the difference in calculated versus counted RFi. Indeed, we measured a substantial number of unidirectional replication forks in mES cells using DNA combing amounting to 13% of the total forks detected (Figure 7F). On the other hand, the combination of a less compacted chromatin in mES cells (Supplementary Figure S14) and the resolving power of the 3D-SIM system allows to visualize more individual replication forks in mouse ES cells. Another possibility that could affect the spatial positioning of replication forks or replicons is a different chromatin loop organization in mES cells at sites of ongoing DNA replication, e.g. by subdivision into multiple smaller loops. Hence, we may also detect more individual forks, increasing the number of observed nano replication foci. The differences in heterochromatin compaction in embryonic stem cells (Supplementary Figure S14) are representative of a chromatin organization that is generally more open than that of differentiated cells (78,98). This, in turn, could affect the organization of the DNA fiber, i.e., into chromatin loops. In support of this, it was reported using chromosome conformation capture carbon copy (5C) that the organization of TADs (topologically associated domains) into multiple sub-megabase sized domains (i.e. sub-TAD domains located within TADs) is found in several developmentally regulated genetic loci in mouse ES and neuronal progenitor (NP) cells. Interestingly, in mES cells, a series of on average 100 kb sized loops connects the Sox2 gene during the ~11 h of S-phase (time progression arrow not scaled). (Sub)chromosomal elements were found to replicate at specific time points during genome duplication. While telomeres located at the long arm of the chromosome replicate throughout S-phase, the ones capping the arms show significant increase in replication during S-phase stage II. In contrast to somatic mouse cells, (per)centromeric DNA (marked in green) replicates during mid S-phase (stage II). The Y chromosome is replicated synchronously at the end of S-phase (stage Y) in pluripotent as well as in differentiated cells. Replication timing of pericentromeric DNA switches from early/mid to late S-phase upon mES cell differentiation, which correlates with chromocenter compaction and decreased histone acetylation. At the molecular level, mES cell replicons are characterized by short inter-origin distances of about 90 kb. Replication forks progress at 1.7 nucleotides per minute to replicate the 5.2 Gb mouse genome in about 11 h. Replication is initiated from around 3320 replication foci (RFi), although theoretically ~2380 bidirectional mES cells are sufficient for genome duplication within the timeframe of S-phase. Hence, from the 3320 sites observed, 28% correspond to single forks and the remaining to bidirectional forks. This is within the range of (13%) single forks observed in DNA fiber analysis. A characteristic arising from the molecular parameters of DNA replication in mouse pluripotent cells are smaller replicon sizes in mES cells relative to somatic cells. Along a given segment of chromosomal DNA carrying multiple licensed origins of replication, mES cells initiate DNA replication from double the number of origins compared to somatic cells. This results in more but smaller replicons and concomitantly smaller inter-origin distances (~90 kb in mES cell and 160–190 kb in mouse/human somatic cells).
with a presumed downstream enhancer element marked by specific histone modifications. Akin to the loss of these epigenetic marks upon differentiation to NP cells, looping interactions were no longer detected in the latter, suggesting a mES cell specific loop organization (136) with loop sizes reflecting replicon sizes that we determined in this study (~90 kb).

In summary, we analyzed the spatio-temporal dynamics of DNA replication progression in (un)differentiated mouse embryonic stem (mES) cells and compared it with somatic cells. We find a developmental switch in the replication order of main chromosomal domains that is dependent on histone acetylation level (Figure 8). Furthermore, we measured and compared the molecular properties of the mES cell replicon, including the number of replication foci active in parallel and their spatial clustering in mES cells versus somatic cells. We conclude that each replication nanofocus in mES cells corresponds to an individual replicon, with approximately one tenth to one quarter representing unidirectional forks. Furthermore, we find that mES cells activate twice as many origins spaced at half the distance than somatic cells. Altogether, our results highlight fundamental developmental differences on progression of genome replication and origin activation in pluripotent cells.

SUPPLEMENTARY DATA
Supplementary Data are available at NAR Online.

ACKNOWLEDGEMENTS
We thank Manuela Milden and Diana Imblan for excellent technical assistance. We are indebted to Sylvia Ritter (GSI Helmholtzzentrum für Schwerionenforschung, Darmstadt, Germany) for helping with embryonic stem cell metaphase spreads and to Kai Breitwieser for help with E14 pulse chase experiments. We thank Alexander Rapp, Kathrin S. Heinz, Florian D. Hastert and Anne K. Ludvig for experimental advice and discussions.

Author contribution: C.R. performed experiments for Figures 1, 2, 4, 5, 8, S10, S14, S15, S18 and S19. P.W. performed experiments for Figures 1, 3–7, S6, S8, S11, S15–S17 and S19. A.M. and H.L. provided the 3D SIM imaging in Figures 1 and 5. A.L. performed growth curve measurement in Figure 4.

C.R. analyzed data from Figures 1–7, S8, S10, S14, S15, S17–S19. Data analysis from Figures 1, 4–7, S8, S11, S15, S16 and S19 were done by P.W. P.P. performed genome wide origin mapping analysis shown in Figures 7D, 7E, S20–S22. D.H. performed RFi feature analysis from Figure S12 and S13. V.O.C. contributed to image analysis. C.R., P.W., C.C.-D. and M.C.C. conceived the project, C.R. generated final figures and C.R. and M.C.C. wrote the manuscript. All authors revised, commented and agreed on the manuscript.

### Supplementary Table 1: Cell line characteristics.

| Name          | Species       | Type             | Genotype | Reference |
|---------------|---------------|------------------|----------|-----------|
| J1 wt         | Mus musculus  | embryonic stem cell | wildtype | (1)       |
| E14 wt        | Mus musculus  | embryonic stem cell | wildtype | (2)       |
| C2C12         | Mus musculus  | myoblast         | wildtype | (3)       |
| MEF W8        | Mus musculus  | embryonic fibroblast | wildtype | (4)       |
| Primary fibroblast | Mus musculus | primary ear fibroblast* | wildtype | -         |

* from adult C57BL/6 mice.

### Supplementary Table 2: Plasmid characteristics.

| Name            | pc number* | Fluorophore | Gene species   | Promoter | Reference |
|-----------------|------------|-------------|----------------|----------|-----------|
| pmRFP-PCNA      | 1054       | mRFP        | Homo sapiens   | CMV      | (5)       |
| pMaSat-GFP      | 1803       | GFP         | -              | CMV      | (6)       |
| pGBP-MaSat      | 2469       | -           | -              | CMV      | (7)       |
| peGFP-HDAC1     | 2447       | eGFP        | Homo sapiens   | CMV      | This study |
| peGFP-C1        | 592        | eGFP        | Aequorea victoria | CMV  | Clontech Laboratories, Mountain View, CA, USA |

* pc: plasmid collection.
### Supplementary Table 3: Nucleotide characteristics.

| Name                     | Application                                      | Detection           | Cat #                | Company                                      |
|--------------------------|--------------------------------------------------|---------------------|----------------------|----------------------------------------------|
| Biotin-16-dUTP           | Labeling of FISH probes                          | Streptavidin        | -                    | Self made (8)                                |
| Dig-11-dUTP              | Labeling of FISH probes                          | Antibody detection  | 11573152910          | Sigma-Aldrich, St Louis, MO, USA             |
| Cy3-dUTP                 | Labeling of FISH probes                          | -                   | PA53022              | GE Healthcare, Chicago, IL, USA              |
| Cy5-dUTP                 | Labeling of FISH probes                          | -                   | PA55022              | GE Healthcare, Chicago, IL, USA              |
| dATP, dTTP, dCTP & dGTP | Generation of FISH probes                        | -                   | 10297018             | Thermo Fisher Scientific, Waltham, MA, USA   |
| 5-ethynyl-2'-deoxyuridine (EdU) | Labeling of nascent DNA in pulse (chase) experiments | ClickIT chemistry   | E10415               | Thermo Fisher Scientific, Waltham, MA, USA   |
| 5-bromo-2'-deoxyuridine (BrdU) | Labeling of nascent DNA in pulse (chase) experiments | Antibody detection  | B5002                | Sigma-Aldrich, St Louis, MO, USA             |
| Thymidine                | Labeling of nascent DNA in pulse (chase) experiments | -                   | T9250                | Sigma-Aldrich, St Louis, MO, USA             |
| 5-ido-2'-deoxyuridine (IdU) | Labeling of nascent DNA in molecular DNA combing experiments | Antibody detection | I7125                | Sigma-Aldrich, St Louis, MO, USA             |
| 5-chloro-2'-deoxyuridine (CldU) | Labeling of nascent DNA in molecular DNA combing experiments | Antibody detection | C6891                | Sigma-Aldrich, St Louis, MO, USA             |

* fluorescence in situ hybridization, ** added only during chase period in pulse chase experiments.
## Supplementary Table 4: Primary and secondary antibody characteristics.

| Reactivity                        | Host    | Dilution | Application          | Cat #     | Company                                |
|-----------------------------------|---------|----------|----------------------|-----------|----------------------------------------|
| anti-PCNA (PC-10)                 | Mouse   | 1:100    | IF*                  | M0879     | Dako, Hamburg, Germany                 |
| anti-Oct3/4 (40/Oct-3)            | Mouse   | 1:1000   | IF                   | 611203    | BD Bioscience, San Jose, CA, USA       |
| anti-H3K9ac (B10)                 | Mouse   | 1:500    | IF                   | 61251     | Active Motif, La Hulpe, Belgium        |
| anti-BrdU/IdU (B44)               | Mouse   | 1:200    | Molecular combing IF | 347580    | Becton Dickinson, Franklin Lakes, NJ, USA |
| anti-ssDNA (16-19, IgG2a)        | Mouse   | 1:200    | Molecular combing IF | MAB3034   | Millipore, Burlington, MA, USA         |
| anti-Sox2 (EPR3131)              | Rabbit  | 1:200    | IF                   | ab92494   | Abcam, Cambridge, UK                   |
| anti-H4K8ac                      | Rabbit  | 1:100    | IF                   | 06-760    | Upstate, Lake Placid, NY, USA          |
| anti-H3K9m3                      | Rabbit  | 1:200    | IF                   | 39161     | Active Motif, La Hulpe, Belgium        |
| anti-H4K5ac (EP1000Y)            | Rabbit  | 1:500    | IF                   | 1808      | Epitomics, Burlingame, CA, USA         |
| anti-digoxigenin                 | Rabbit  | 1:500    | FISH** probe detection | 700772    | Thermo Fisher Scientific, Waltham, MA, USA |
| anti-BrdU/CldU (BU1/75 (ICR1))   | Rat     | 1:100/1:200 | IF/Molecular combing IF | OBT0030CX | BioRad, Puchheim, Germany |
| anti-GFP (7.1 & 13.1)            | Mouse   | 1:500    | FISH IF              | 11814460001 | Roche, Penzberg, Germany |
| anti-mouse Alexa488              | Donkey  | 1:300    | IF (fluorescent secondary) | 715-545-150 | The Jackson Laboratory, Bar Harbor, ME, USA |
| anti-mouse IgG Cy3               | Donkey  | 1:300    | IF (fluorescent secondary) | 715-165-151 | The Jackson Laboratory, Bar Harbor, ME, USA |
| anti-mouse IgG Chromo 546        | Goat    | 1:200    | Molecular combing IF (fluorescent secondary) | 15033 | Active Motif, La Hulpe, Belgium |
| anti-mouse IgG AlexaFluor 594    | Donkey  | 1:500    | IF (fluorescent secondary) | 715-585-151 | The Jackson Laboratory, Bar Harbor, ME, USA |
| Reactivity                  | Host      | Dilution | Application                           | Cat #     | Company                                      |
|----------------------------|-----------|----------|---------------------------------------|-----------|----------------------------------------------|
| anti-mouse IgG Alexa647    | Goat      | 1:300    | IF (fluorescent secondary)            | A-32728   | Molecular Probes Inc., Eugene, OR, USA       |
| anti-mouse IgG2a AlexaFluor 647 | Goat  | 1:200    | Molecular combing IF (fluorescent secondary) | A-21241   | Fisher Scientific GmbH, Hampton, NH, USA    |
| anti-rabbit IgG Cy3        | Donkey    | 1:300    | IF (fluorescent secondary)/FISH probe detection | 711-165-152 | The Jackson Laboratory, Bar Harbor, ME, USA |
| anti-rabbit IgG Alexa647   | Goat      | 1:300    | IF (fluorescent secondary)            | A-21245   | Molecular Probes Inc., Eugene, OR, USA       |
| anti-rat IgG AlexaFluor 488 | Donkey  | 1:500/1:200 | IF/Molecular combing IF (fluorescent secondary) | 712-545-153 | The Jackson Laboratory, Bar Harbor, ME, USA |

* IF: immunofluorescence, ** fluorescence in situ hybridization.
## Supplementary Table 5: Imaging systems characteristics.

| Microscope/ Company | Lasers/lamps                                                                 | Filters (ex. & em. [nm])* | Objectives/ lenses | Detection system | Incubation system | Application                                      |
|---------------------|------------------------------------------------------------------------------|---------------------------|--------------------|------------------|-------------------|--------------------------------------------------|
| Ultra-View VoX spinning disk on an inverted Nikon Ti-E microscope/ PerkinElmer Life Sciences, UK | solid state diode lasers (405 nm, 488 nm, 561 nm, 640 nm) | 405/488/568/640**       | oil immersion 60x Plan-Achromat (NA 1.45) | cooled 14-bit Hamamatsu® C9100-50 EMCCD | closed live-cell microscopy chamber (ACU control, Olympus) for time-lapse microscopy | time-lapse microscopy & confocal z-stack imaging |
|                     |                                                                               |                           |                    |                  |                   |                                                  |

SUPPLEMENTARY FIGURES

segmentation of crowded nuclei (3D)
- DAPI confocal stacks (cropped)
  - include a subset of the images into a "Pixel classification" project
  - select all features (features with σ<=1 calculated in 3D, larger σ in 2D)
  - manually annotate some pixels as background, nuclear border, nuclear interior
  - train the default random forest classifier and apply to the rest of the images
  - export probabilities for all 3 classes as TIFF or HDF5
  - same steps as in DAPI segmentation
  - only two classes: background & RF
  - export simple segmentation or: export probabilities and threshold at 0.5
  - manually annotate one region in each nucleus
  - export labels
  - separate touching objects via watershed transform using extrema of the Euclidean Distance Transform (EDT) as seeds and the inverse EDT as the ridge image
  - remove segmented objects with overlap < 50% with nuclear mask
  - aggregate all measurements for a file: RF count, median of each feature of individual RF, standard deviation of each individual feature

segmentation of RFi (3D)
- EdU confocal stacks
- include a subset of the images into a "Pixel classification" project
- manually annotate one region in each nucleus
- export labels
- separate touching objects via watershed transform using extrema of the Euclidean Distance Transform (EDT) as seeds and the inverse EDT as the ridge image
- remove segmented objects with overlap < 50% with nuclear mask
- aggregate all measurements for a file: RF count, median of each feature of individual RF, standard deviation of each individual feature

feature extraction
- zoom raw images and nucleus & RFi masks in z for isotropic resolution of 57 nm (cubic interpolation)
- calculate EDT of nuclear mask
- calculate features for each object in RF segmentation (region properties):
  - shape features: solidity, extent
  - location features: distance to nuclear border (mean of nuclear EDT under RF), distance to nearest neighbor RF: mean distances to 3 nearest RF and 5 nearest RFi
  - intensity features: mean DAPI & EdU intensity in the object & mean normalized DAPI & EdU intensity (normalized to 5% and 99% quantile within nuclear mask)
- exclude objects smaller than 200 px (~1 confocal PSF)
- aggregate all measurements for a file:
- save as CSV for downstream analysis/visualization
**Supplementary Figure S1 – Analysis pipeline of replication foci (RFi) features.** To extract quantitative features of RFi, DAPI stained nuclei and EdU labeled RFi were segmented in confocal stacks of mES cells. The central nucleus as well as RFi were segmented using supervised pixel classification (ilastik) and watershed transform (Python with scipy/scikit-image). Several features were calculated for each RF and used to create an aggregate feature vector for each image. A detailed analysis pipeline is described in the Materials and Methods section.
select mid slice for DAPI and histone modification channel

select G1 phase cells according to DAPI signal intensity

duplicate middle plane:
image > Duplicate
select “OK”

draw ROIs

with duplicated image:
DAPI channel:
select 4 circular ROIs INSIDE chromocenters
select 4 circular ROIs OUTSIDE chromocenters
-> every ROI to the ROI manager

with duplicated image:
histone channel:
import the 8 ROIs
> measure intensity

measure histone modification levels in chromocenters and in nucleoplasm
Supplementary Figure S2 – Analysis pipeline of histone modification levels. To determine the histone modification levels at chromocenters, DAPI intensities of all cells were measured at middle planes and cells were grouped into G1, S and G2 phases, accordingly. Four circular regions of interest (ROI) were drawn in middle plane G1 phase cells inside DAPI intense stained chromocenters. Similarly, four circular ROIs were drawn outside of chromocenters and intensity levels within these ROIs were measured in the histone modification channel. A detailed analysis pipeline is described in the Materials and Methods section.
open multi-channel and multi-sliced image in ImageJ & create nuclear masks

with DAPI images:
(1) draw manual ROIs around individual nuclei in several planes & add to ROI Manager
mark ROIs > 'right-click' > Interpolate ROIs
File > New > Image (with same dimension & slices and black background)
create binary image from all ROIs: 'right-click' on ROI Manager > Fill

(2) segment FISH signals

create 3D nucleus ROIs

(3) use Plugins > 3D > 3D Manager > 'Add Image' (create 3D ROI of binary image from (1))
(4) apply 3D ROI to segmented FISH signals from (2)

apply 3D nucleus ROI to FISH signals

(5) open second 3D Manager > 'Add Image' to import ROIs for FISH signals from within the 3D ROI from (3)
Note: some 3D FISH ROIs might be deleted manually due to overlap with neighbouring cells

apply 3D FISH ROIs to PCNA channel

(6) apply 3D FISH ROIs from (5) to PCNA channel

measure PCNA intensities
Supplementary Figure S3 – Analysis pipeline of Repli-FISH analysis. To determine the replication timing of specific (sub)chromosomal elements, 3D masks of individual cell nuclei were manually generated based on the DAPI channel. FISH signals were segmented. The 3D nucleus mask was applied to the segmented FISH signals and the generated nuclear FISH ROIs were used to mask the PCNA signals and PCNA intensities within the mask were measured. A detailed analysis pipeline is described in the Materials and Methods section.
convert 3D-SIM raw images to 16-bit images

duplicate stack:
Image > Duplicate
Select “Duplicate Stack”
Select “OK”

segment replication foci via auto-thresholding using the Triangle method

with duplicated image:
Image > Adjust > Autothreshold
choose “Triangle Method”
select “Ignore black”
select “White objects on black background”
select “Stack”
select “Use stack histogram”
select “OK”

mask the original replication foci

mask the original image:
choose Process > Image Calculator
Image1: Choose thresholded image
specify method: “Min”
Image2: Choose original image
select “Create New Window”
select “OK”

→ save resulting masked image

import DAPI and masked replication images to Volocity

select newly generated folders
generate stack > Tools > Make volumes
set pixel sizes > Edit > Properties

create nucleus mask with DAPI image & segment replication foci

with DAPI image:
choose “Measurements”
> Find objects
> Close
> Fill holes in objects
> Exclude objects by size (200 μm³)
> Make ROI from populations

with replication foci image:
choose “Measurements”
> Find objects using intensity
> Select wheel > choose “Lower”
> Separate touching objects (0 μm³)
> Exclude objects by size (0.0002 μm³)
> Exclude not touching ROI

count replication foci within nucleus (DAPI mask)
Supplementary Figure S4 – Analysis pipeline of 3D structured illumination microscopy (3D-SIM) resolved nano replication foci counting. For counting of nano replication foci (nanoRFi) in 3D-SIM images, analysis was done using ImageJ and the PerkinElmer Volocity software. Raw image files were converted to 16-bit images, individual cell nuclei were segmented based on the DAPI channel, replication signals were thresholded and the binary images were used to mask the original replication foci signals. DAPI and masked replication foci images were imported to Volocity to quantify replication foci for individual nuclei by creating nuclear masks and corresponding ROIs (regions of interest) were based on the DAPI images. Next, 3D-SIM replication foci were detected by intensity and only foci within the nuclear ROI were counted. A detailed analysis pipeline is described in the Materials and Methods section.
convert pWF raw images to match dimensions of 3D-SIM images

match image dimensions (40x40x125 nm):
> double pixel numbers via a bicubic interpolation
> pixel shift correction via translation of -2 pixels in x and y:
  > Image
  > Transform
  > Translate

segment pWF replication foci via auto-thresholding using the Otsu method

duplicate stack
generate stacked image:
  > Process > Enhance contrast > Saturated Pixels = 0% & check "Normalize histogram"
  > Process > Subtract background (rolling ball algorithm with radius = 10)
  > Image > Adjust > Autothreshold
choose "Otsu Method"
select "Ignore black"
select "Ignore white"
select "Stack"
select "Use stack histogram"
select "OK"
mask the original image:
  > Image Calculator:
    Image1: Choose thresholded image
    specify method: "Min"
    Image2: Choose original image
    select "Create New Window"
    select "OK"

→ save resulting masked image

import masked pWF and 3D-SIM images to Velocity

select newly generated folders
generate stack > Tools > Make volumes
set pixel sizes > Edit > Properties

with pWF RFi image:
choose "Measurements"
  > Find objects using intensity

merge pWF and 3D-SIM images:
choose "Actions"
  > Create
  > Image sequence from selection

analyze overlapping RF foci:
in "Measurements" tab
  > Intersect: nanoRFi (3D-SIM)
    With: pWF RFi
  > Compartmentalize

analyze overlap of nanoRFi and pWF RF
Supplementary Figure S5 – Analysis pipeline of nano replication foci per pseudo-widefield replication focus quantification. For counting nano replication foci (nanoRFi) per pseudo-widefield (pWF) replication focus, analysis was done using ImageJ and the PerkinElmer Volocity software. Dimensions of pWF replication raw images were matched to the image dimension of the 3D-SIM data (40 x 40 x 125 nm). Individual cell nuclei were segmented based on the DAPI channel, histograms of replication signals were normalized, background was subtracted, signals were thresholded and the binary images were used to mask the original replication foci signals. 3D-SIM replication signals were processed as described in Supplementary Figure S4. Segmented and masked pseudoWF and 3D-SIM image stacks were imported to Volocity and merged. Detection of pWF RFi was based on intensity as for 3D-SIM images and the number of nanoRFi contained in one pWF RF were counted.
Supplementary Figure S6 – Analysis of the mouse embryonic stem cell replicon by DNA fiber assays. (A) Classification of typical DNA fiber signals obtained from molecular combing experiments. Replication fork speed is calculated from measurements of green replication signals (arrows) flanking red tracks that mark initiation events during the first pulse labeling period (origins of replication marked by black arrowheads). Merging forks within clusters of origins and termination events are discarded (marked with X). Fork asymmetry can be assessed by calculating the ratio of left/right replication forks, emanating from an origin of replication. Replication signals spreading in only one direction are considered as unidirectional replication forks. (B) Representative examples of replication signals from DNA combing experiments. Labeling is according to the classification described in (A). The inter-origin distance (IOD) is the distance between neighboring initiation sites within a cluster, identified based on the first nucleotide label (IdU, red).
Supplementary Figure S7 – Statistics representation using violin plots. Statistical analyses were represented by violin plots, a variation of boxplots with a kernel density plot on each side. Similar to a boxplot, boxes and whiskers represent 25–75 percentiles and 1.5 times the IQD (inter-quartile distance), respectively and the center line depicts the median. Additionally, violin plots represent the probability density of the data at different values.

Supplementary Figure S8 – Live-cell analysis of DNA replication dynamics in mouse embryonic stem cells. (A) J1 mES cells were transfected with mRFP-PCNA and stained with a PCNA specific antibody. Representative confocal images of the anti-PCNA staining (grey) in an mRFP-PCNA (magenta) transfected and an untransfected cell are shown. (B) MaSat-GFP polydactyl zinc finger (PZF) transfected cells were fixed using a formaldehyde gradient with simultaneous permeabilization and major satellite repeat sequences were visualized by fluorescence in situ hybridization (FISH) with a MaSat specific probe (green). Representative confocal images are shown. (C) mES cells were co-transfected with plasmids encoding fusion constructs of mRFP-PCNA (magenta) and GFP-tagged polydactyl zinc finger protein binding to major satellite sequences (MaSat-GFP, green) to follow S-phase progression and to mark pericentromeric heterochromatin (chromocenters), respectively, and imaging was performed for 24 hours with 30 minutes intervals. Spinning disk confocal images of a representative cell progressing through S-phase (stage I to IV?) and G2 phase. (D) Approximate durations of the individual substages (mean ± StDev) were calculated from at least 15 cells (Supplementary Table 7) from different live cell experiments. The arrowheads in the IV? stage mark a prominent accumulation of replication signals observed at the end of S-phase. Scale bar = 5 µm.

Supplementary Figure S9 – Description of the pulse chase experiments. (A) Experimental setup of a pulse-chase experiment to determine the spatio-temporal progression of DNA replication in mES cells. Asynchronously growing mES cell cultures were pulse labeled with the nucleotide analog EdU, followed by various thymidine chase periods (white arrows) and fixation. Subsequently, replication foci marked by the incorporated EdU, i.e. nascent DNA during the first pulse labeling (cyan), and the replisome component PCNA, i.e. ongoing replication at the time point of fixation (magenta), were (immuno)fluorescently detected (Figure 1C). The different chase times resulted in different degrees of replication foci separation and, with increasing chase times, eventually also to transition from one S-phase pattern to the next. Representative confocal images of EdU pulsed cells followed by different chase times before fixation, are shown. (B) Schematic overview of the S-phase progression with different chase durations. Durations of the different S-phase stages are indicated on the left. Chase durations in the fixed cell approach were changed according to S-phase substage duration. While shorter chase times (< 2 hours/ 2.5 hours for stage I - II and II - III, respectively and < 0.75 hours for stage III - IV and IV - IV transitions) do not visualize substage transitions in a substantial amount of cells, increasing chase times reveals changes in S-phase patterns. This approach allowed us to get a spatio-temporal resolution of DNA replication in fixed cells. (C) Schematic representation and representative confocal images of a pulse-chase-pulse-chase experiment, underlining the domino-like DNA replication model. Scale bars = 5 µm.
Supplementary Figure S10 – DNA replication dynamics of mouse embryonic cells in different microenvironments. (A) J1 mES cells were pulse chased as described in Figure 1, 6 hours (single cells) or 24 hours (colonies) after seeding, EdU and PCNA were (immuno)fluorescently detected and S-phase progression was analyzed. Representative confocal images of cells passing from stage I to stage II are depicted for single cells and cells grown in colonies. (B) J1 mouse ES cells were grown for 15 days in medium containing only LIF or 2i and LIF and pulse chased 24 hours after seeding. Confocal images of S-phase progression from stage I to stage II are depicted as above. Scale bars = 5 µm.
Supplementary Figure S11 – DNA replication dynamics in mouse E14 embryonic stem cells.

The experimental pulse chase setup (described in Figure 1), allowed the identification and temporal order of five main replication patterns in mouse E14 ES cells. Representative spinning disk confocal images of transitions from G1 to S-phase, S-phase substage transitions and S-phase to G2 progression are shown. The arrowheads in the IV? stage mark a prominent accumulation of replication signals observed at the end of S-phase. White arrows represent chase periods. Scale bar = 5 µm.
Supplementary Figure S12 – Characteristics of replication foci in the five S-phase substages of mouse embryonic stem cells. Replication foci (RFi) distance from the nuclear border, RFi solidity, RFi numbers and normalized DAPI intensities within RFi are plotted for the five different mES cell S-phase stages. Cyan marked boxplots represent features that differ significantly from one stage to the other. All boxplots are as in Figure 2 and Supplementary Figure S7. Detailed statistics are summarized in Supplementary Table 7.
Supplementary Figure S13 – t-distributed stochastic neighbor embedding (t-SNE) analysis and replication foci (RFi) characteristics distributions. (A) t-SNE embedding was used to visualize the high-dimensional RFi characteristics. Each high-dimensional object was modeled by a 2 dimensional point. Similar objects are modeled by nearby points and dissimilar objects are modeled by distant points. Six variants of t-SNE representations are shown. Multinomial logistic regression of the S-phase stage from the image features reached >70% accuracy. When also allowing for one-off errors (e.g. stage I classified as II), the accuracy was over >90% (accuracy determined in 5-fold cross-validation).
Supplementary Figure S14 – Characteristics of pericentromeric DNA clusters (chromocenters) in (un)differentiated mouse embryonic stem cells and mouse myoblast cells. (A) Representative cell nuclei from undifferentiated J1 mES cells (cyan), differentiated J1 mES cells (blue) and primary mouse ear cells (magenta). Average numbers of chromocenters per cell (B), volumes of chromocenters (C), chromocenter compaction (coefficient of variation of DAPI (StDev/mean, D)) and chromocenter shape factor (E) show the different organization of pericentromeric heterochromatin in mouse somatic and pluripotent mES cells. In (D), condensed chromatin is characterized by high DAPI intensities. Thus, cell nuclei containing condensed chromatin show a higher DAPI standard deviation than cells containing decondensed chromatin, which is characterized by low DAPI standard deviations. Normalized DAPI standard deviation values, as a proxy for DNA decondensation levels, are plotted. All boxplots are as in Figure 2 and Supplementary Figure S7. Detailed statistics are summarized in Supplementary Table 9. Scale bar = 5 µm. * P < 0.05.
Supplementary Figure S15 – Validation of FISH probes for (sub)-chromosomal elements. (A) Schematic overview of the chromosomal location and sequence motifs of the analyzed major and minor satellites (MaSat (cyan) and MiSat (magenta)) and telomere (green) repeat elements in mouse cells. (B) Triple-color FISH combining probes labeled with different nucleotide analogs, specific for major satellites (cyan), minor satellites (magenta) and telomeres (green) hybridized to metaphase chromosome preparations from diploid mouse cells. Insets show a magnification of one chromosome and arrows show specific probe binding. (C) Schematic overview of the mouse Y chromosome and the primer sequence used for probe generation (left). Hybridization of the Y chromosome specific probe to mouse metaphase spreads. Inset shows specific probe annealing to one chromosome (right). Scale bar = 10 µm and 1 µm for main graphs and magnified regions, respectively.
Supplementary Figure S16 – Replication timing of (sub-)chromosomal structures in mouse embryonic stem cells. Tandem repeat elements (magenta, major satellites (MaSat, (A)), minor satellites (MiSat, (B)) and telomeres (C)) and the Y chromosome (D) were co-visualized with PCNA (grey) via Repli-FISH in mES interphase cells. Cells were classified into S-phase stages I to Y according to their PCNA pattern, mean PCNA intensities within the marked elements were measured as described in Supplementary Figure S3 and plotted. Red boxes represent mean ± 95% confidence intervals and mean values are indicated below each plot. DAPI (grey) and hybridization signals (magenta) are shown as a merge. Dotted lines represent cell contours. Detailed statistics are summarized in Supplementary Table 10. Scale bar = 5 µm.

- 

** Additional notes and explanations based on the images provided. **
Supplementary Figure S18 – Replication timing of subchromosomal structures and the Y chromosome in mouse embryonic stem cells. EdU (DNA replication) and the Y chromosome were co-visualized with major satellite repeats and telomeres (A), with major and minor satellite repeats (B) and with minor satellite repeats and telomeres (C) in mES cell interphase nuclei. Cells were classified into S-phase stages I to Y according to their EdU pattern, mean EdU intensities within the marked elements were measured as described in Supplementary Figure S3 and plotted. Detailed statistics are summarized in Supplementary Table 10. Scale bar = 5 µm. * P < 0.05 (calculated among the same element against the respective stage I value).

**Figure S19 – Y chromosome replication marks the end of S-phase independently of the cell potency state.** (A) Replication timing analysis of the Y chromosome in mouse embryonic fibroblasts (MEF) via Repli-FISH. PCNA quantification within hybridization signals and representation are as in Figure 4. (B) Pulse chase experiment in male (un)differentiated mouse J1 ES cells and mouse embryonic fibroblasts (MEF W8). Representative spinning disk confocal images of transitions from stage III/late to stage Y and from stage Y to G2 are shown for all three cell lines. Arrowheads mark the Y chromosome. Boxplots are as in Figure 2 and Supplementary Figure S7. Scale bar = 5 µm. Detailed statistics are summarized in Supplementary Table 10. * P < 0.05 (calculated against S_Y).
Supplementary Figure S20 – Origin profiling in mouse embryonic stem cells, mouse embryonic fibroblasts and mouse activated B cells. Graphical representation of origin profiling in mES, MEF and mouse activated B cells (act. B cells) in all replicates analyzed are shown. mES and MEF origins clustered at the distance of 22 kb (performed for equalization of origin mapping resolution in the SNS-seq and the OK-seq methods) as well as the middle point of clustered origins are indicated. The OK-seq profiles in the B cell line in 3 replicates are represented in the following rows as well as origins localization and their middle point. The replication profile scale is indicated in the upper left corner.
Supplementary Figure S21 – Origin distribution on the chromosome X and autosomal chromosomes. (A) The comparison of IOD calculated for the mES and MEF cell lines on autosomes and the chromosome X using the SNS-seq origin mapping data. (B) Schematic representation of origin distribution on the chromosome X and 2 parental copies of autosomal chromosomes. (C) Graphical representation of origin profiling in mES and MEF cells on a somatic chromosome (chromosome 12) and an arbitrary chosen region on the chromosome X. Two independent replicates of origin profiling and the localization of origins reproducibly identified in the two replicates are shown. The replication profile scale is indicated in the upper left corner. Detailed statistics are summarized in Supplementary Table 13. * $P < 0.05$. 
Supplementary Figure S22 – Origin mapping resolution in genome-wide techniques and origin clustering. (A) Origin mapping resolutions measured as an average origin peak width in SNS-seq and OK-seq methods are shown. (B) For comparison purposes the differences in methods resolution were equalized by merging the neighboring origins detected in SNS-seq in the distance of the average peak size in OK-seq analysis (22 kb). The IODs calculated for clustered origins in mES and MEF cell lines as well as origins identified in activated B cells (act. B cells) are shown. Detailed statistics are summarized in Supplementary Table 13. * $P < 0.05$.

Movies 1 & 2 - Time lapse movie of cell cycle progression in a mouse embryonic stem cell. mES cells were transfected with mRFP-PCNA and MaSat-GFP (polydactyl zinc finger protein with specific binding to major satellite repeats) and time lapse confocal microscopy was performed 24 hours post-transfection. z-stacks were acquired at 30 minutes intervals. Chromocenters (green) and DNA replication (magenta) are shown as merged images and time intervals are shown on the upper left. Depicted mES cell progresses from S-phase stage I to mitosis (movie 1) and from S-phase stage I to G2 (movie 2). Scale bar = 5 µm.
