Case Report

A rare case of retroperitoneal and mesenteric lymphangiomatosis

Lymphangiomatosis are rare benign malformations of the lymphatic system. They are more commonly seen during childhood and are frequently asymptomatic and incidentally found in the adult patient. We report a case of a 31-year-old male who presented initially with melena. Computer tomography scan revealed multiple confluent, fluid-density lesions encasing the retroperitoneum and mesentery. A laparotomy and incisional biopsy of the mesenteric lesion was performed. Histologic examination demonstrated fibrofatty tissue with prominent, thick-walled endothelial-lined vessels. The histologic and computer tomography findings were consistent with a diagnosis of retroperitoneal and mesenteric lymphangiomatosis. The patient was subsequently discharged home well.

**Introduction**

Lymphangiomatosis are rare, benign malformations of the lymphatic vessels. It is usually diagnosed during childhood and are usually incidentally diagnosed in asymptomatic adults. These lesions are preferentially located in the neck and axilla, and abdominal lymphangiomatosis are uncommonly encountered. We report a case of a 31-year-old male presenting with melena and incidentally diagnosed with retroperitoneal and mesenteric lymphangiomatosis.

**Case presentation**

A 31-year-old male presented to our institution with a one day history of melena for investigation. The patient had a background of recurrent gastrointestinal (GI) bleeding as evidenced by 2 separate episodes of melena that occurred a month and a week prior to this presentation. Oesophagogastroduodenoscopy performed during those episodes revealed a Forrest III D1 ulcer and a Forrest IA D1 ulcer respectively. These were successfully treated endoscopically with hemoclips and...
adrenaline injection. Physical examination did not reveal any abnormalities apart from conjunctival pallor. No abdominal masses were noted. Significant laboratory investigations included anemia (Hemoglobin 6.5 g/dL) and hypoproteinemia (Albumin 20 g/L). Coagulation profile was within normal limits.

An urgent oesophagogastroduodenoscopy was performed which did not reveal any active bleeding. Subsequently, patient developed further episodes of melena requiring a repeat attempt at endoscopic hemostasis. This was unsuccessful and a computer tomography (CT) angiogram was performed for the patient with a view for interventional radiological management of the bleeding D1 ulcer. However, this did not demonstrate any active bleeding. The patient’s bleeding spontaneously resolved thereafter and he was maintained on proton pump inhibitors.

Incidentally, the CT angiogram revealed multiple confluent, fluid-density lesions encasing the mesenteric and retroperitoneal vessels (Figs. 1 and 2). Given the radiological findings, our initial concern was to evaluate for chronic infection or malignancy. Infective markers including tests for tuberculosis and human immunodeficiency virus were negative. A pan-CT scan of the patient demonstrated lobulated, fluid density cystic lesions around the mesenteric root encasing the mesenteric vessels (see Fig. 2). No other lesions in the rest of the body were identified on the pan-CT. Bone marrow aspirate did not reveal any lymphoproliferative disorder.

The patient subsequently underwent elective exploratory laparotomy to obtain tissue samples for histologic analysis. Intraoperatively, diffusely swollen mesenteric tissue with multiple enlarged lymphatic channels were noted. Serous lymphatic fluid was also seen leaking out under pressure after incisional biopsy of the lesion. In view of the extent of mesenteric involvement and presence of dense adhesions, the operation was concluded after the biopsy. Histopathological examination showed fibrofatty tissue with prominent, thick-walled endothelial-lined vessels consistent with a diagnosis of lymphangiomatosis.

Postoperatively, the patient recovered well apart from having postoperative ileus which resolved with bowel rest and drip and suck regimen. There were no more episodes of melena. He was discharged uneventfully on the eighth postoperative day. The patient was reviewed 6 weeks after discharge and found to be asymptomatic with good appetite and bowel habits.

**Discussion**

**Definition**

Lymphangiomatosis are rare, benign proliferative malformations of the lymphatic system. They consist of endothelium-lined spaces surrounded by a connective tissue stroma of varying thickness containing lymphoid tissue, round cells and smooth muscle [1]. Up to 90% of cases are diagnosed within the first 2 years of life [2] and it is rarely diagnosed in adults [1,3]. There is no gender predilection and no familial tendency [2]. Although the exact etiology of the disease remains unclear, its occurrence mainly in the paediatric age group has led researchers to postulate that the disease is due to a congenital abnormality of the lymphatic system [3]. Other secondary causes of lymphangiomatosis include abdominal trauma, surgery, radiation, lymphatic obstruction or inflammatory processes [4].

Lymphangiomatosis have been reported in almost all body organs but the brain, which does not contain lymphatic tissue [5]. The vast majority (95%) of lesions are located in the neck (known as “cystic hygromas”) and axilla, with the remaining 5% scattered throughout the body [6]. Abdominal lymphangiomatosis account for less than 1% of all cases and typically
affect the retroperitoneum. Intraperitoneal sites include the mesentery and omentum, with the small bowel mesentery accounting for 70% of intraperitoneal disease [7]. Of note, our patient had retroperitoneal and mesenteric disease consistent with data reported in the literature.

**Symptoms/presentation**

There are no pathognomonic symptoms or signs of abdominal lymphangiomatosis and routine laboratory tests are non-specific. Abdominal pain, distention or a palpable abdominal mass are possible findings but patients can present in a variety of ways. As these lesions are essentially pockets of fluid, patients are often asymptomatic and incidentally diagnosed only after abdominal imaging. Alternatively, the patient may present acutely with pain, GI bleeding, intestinal obstruction or bowel perforation [8,9]. Uncommon but potentially life-threatening complications include traumatic cyst rupture, cyst torsion, intestinal volvulus or severe GI bleeding [10].

There are a handful of case reports in the literature [1,11,12] describing adult patients having abdominal lymphangiomatosis with GI bleeding and hypoproteinemia. It has been suggested that hemorrhage into cystic lymphatic spaces resulting in GI bleed could be due to trauma, development of a venolymphatic communication or a developing hemangioma as a tumour component. Hypoproteinemia results from an associated protein-losing enteropathy due to impaired mucosal integrity. Although our patient presented in a similar manner, the association of his bleeding D1 ulcer and abdominal lymphangiomatosis was likely coincidental.

**Investigation**

Plain abdominal radiography cannot diagnose abdominal lymphangiomatosis per se but may detect complications such as intestinal obstruction or bowel displacement from mass effect. Ultrasonography may reveal cystic lesions with internal echoes. Occasionally, the lesions can be complicated by haemorrhage or infection, resulting in echogenic content within. Cross sectional imaging can provide information pertaining to size, anatomical location, degree of organ involvement and presence of complications. Lymphangiomatosis can be differentiated from ascites by its retroperitoneal location, presence of septations, and lack of fluid in the mesenteric leaves as well as the dependent portions of the abdomen and pelvis. On CT, they are seen as uni- or multilocular low density lesions with thin, imperceptible walls. This is seen in our patient’s case as well (see Fig. 3). Lesions are typically of fluid (near 0 HU) or chylos (around -20 HU) density depending on its contents. Rarely, haemorrhage can increase the density of the internal content and be confused with solid masses. Calcifications within the lesions are rare [13]. Lymphangiomatosis have low signal on T1-weighted imaging and high signal on T2-weighted imaging on MRI. With a large amount of chyle, the lesions will demonstrate high signal on T1-weighted images and intermediate signal on T2-weighted images [14].

Occasionally, abdominal lymphangiomatosis incite a marked inflammatory reaction that can mimic acute appendicitis or even a malignant tumour. As such, a definitive diagnosis is usually made postoperatively based on histopathological or immunohistochemical findings. Lining mesothelial cells are immunoreactive for cytokeratin and negative for factor VIIIIs. Double staining with CD31 and Proxim-1 is the most reliable method to demonstrate lymphangioma endothelial cells [7,15].

**Treatment**

Some authors have suggested that the ideal treatment for abdominal lymphangiomatosis is radical surgical excision, even for asymptomatic patients, due to its potential for invasion and/or growth to large sizes [10]. However, surgery may be too risky or technically impossible for disease involving major abdominal structures. Furthermore, Kochman et al advocated that aggressive surgery be avoided in these asymptomatic patients as these lesions are inherently benign [16]. Other reported treatments in the literature include: marsupialization, percutaneous drainage, injection sclerotherapy and biologic response modifiers [17–20]. Owing to the rarity of this disease and the paucity of evidence in the literature, patients should
be managed on an individual basis – taking into account their symptoms, extent of disease and presence of complications. The extensive involvement of the small bowel mesentery and retroperitoneum in our patient rendered radical excision impossible. Furthermore, as the condition was incidentally diagnosed, the procedure was limited to an open incisional biopsy for histologic diagnosis. As he remained asymptomatic on follow-up, no further treatment of the condition was offered.

**Conclusion**

Abdominal lymphangiomatosis is an uncommon disease entity seldom encountered in adult surgical practice. Its presentation may be subtle and varied. CT or MRI is the recommended diagnostic investigation of choice. As the majority of patients are asymptomatic, this condition should be conservatively managed. However, patients presenting with acute complications may require urgent surgical consult and intervention.
