Keywords: Covid-19 Vogt-Koyanagi-Harada disease Uveitis Inactivated vaccine

ABSTRACT

Purpose: We report a case of a 19-year-old male who presented with bilateral Vogt-Koyanagi-Harada (VKH)-like panuveitis following an injection of an inactivated Covid-19 vaccine.

Observations: A 19-year-old male was referred to our clinic with a 2-week history of blurred vision on both eyes and headaches, 12 hours following the administration of the first dose of an inactivated Covid-19 virus vaccine (Sinovac). He denied any past ocular or medical history. Clinical examination and multimodal imaging tests identified serous retinal detachment and choroidal thickening posteriorly and deep yellow foci in the far peripheral retina. Aqueous humor analysis ruled out viral and bacterial infection including Covid-19, but demonstrated an elevated interleukin-6 level. A workup ruled out systemic infection or autoimmune disease. Although the patient received a single positive T-SPOT result, no other clinical evidence supported active tuberculosis infection. Non-infectious panuveitis was diagnosed and treated with periocular steroids that quickly resolved the serous retinal detachment.

Conclusions and Importance: This is the first report of VKH-like uveitis following an inactivated Covid-19 vaccine, with aqueous humor analysis ruling out viral or bacterial infection and demonstrating an elevated interleukin-6 level. Though rare, VKH-like uveitis may be associated with administration of an inactivated Covid-19 vaccine.

1. Introduction

The Covid-19 pandemic has promoted vaccine development at a fast pace. There are currently over 10 vaccines developed and approved for use within 2 years of the pandemic. Since the implementation of vaccine campaigns, reports of ocular adverse effects have emerged. Although uveitis is a rare adverse event, there are reported events following various Covid-19 vaccines including anterior uveitis, multiple evanescent white dot syndrome (MEWDS), acute macular neuro-retinopathy, central serous retinopathy, multifocal choroiditis, and reactivation of Vogt-Koyanagi-Harada (VKH) disease.

VKH-like uveitis is a very rare adverse event of vaccination, and only several cases have been reported worldwide following vaccines against yellow fever, influenza, hepatitis B, and human papilloma virus (HPV), as well as following administration of the bacille Calmette-Guerin (BCG) vaccine. Recently, cases of VKH disease following Covid-19 mRNA and adenovirus vector vaccine have been reported. We report a case of bilateral VKH-like disease following an inactivated Covid-19 virus vaccine.

2. Case report

A 19-year-old male was referred to our clinic with a two-week history of bilateral eye redness and blurred vision. The patient denied any past ocular or medical history. The patient had received the first dose of an inactivated Covid-19 virus vaccine two weeks prior, after which the patient reported headaches and fatigue 2 h later and subsequently developed bilateral blurred vision 12 hours following the vaccination. On examination, the best visual acuity was 20/20 bilaterally and intraocular pressure was 11.2 mm Hg in the right eye and 11.3 mm Hg in the left eye. Anterior segment examination revealed mild conjunctival congestion, gray fine keratic precipitates, and 2+ cells in the anterior chamber in both eyes. Slit lamp examination revealed 1+ cells in the anterior vitreous. Dilated indirect ophthalmoscopic examination revealed 1+ vitreous haze and demonstrated serous retinal detachments and multiple choroidal foci far peripherally in both eyes (Fig. 1), which were further confirmed by optical coherence tomography (OCT) (Fig. 2). Autofluorescence (AF) was unremarkable (Fig. 2). Wide-field fluorescein angiography (FA) showed mild hyper-fluorescence in the posterior fundus.
pole and multiple hyperfluorescent foci inferiorly, more prominent in the left eye (Fig. 3). Aqueous humor was sent for viral and bacterial detection including cytomegalovirus, rubella virus, herpes simplex virus as well as Covid-19 virus, but all yielded negative results. However, inflammatory analysis demonstrated elevated interleukin-6 (IL-6) in both eyes (1024.0 pg/ml OD and 734.6 pg/ml OS). Systemic
investigation was unremarkable, including cranial magnetic resonance imaging, complete blood count, serum rheumatoid factor, antinuclear antibodies, and antineutrophilic cytoplasmic antibodies. Serologic tests for the Covid-19 virus, hepatitis B, herpes simplex virus, human immunodeficiency virus, and syphilis were negative. Although the patient’s interferon gamma release assay (T-SPOT) results were positive, chest X-ray and computed tomography were normal, along with IL-6, C-reactive protein, and erythrocyte sedimentation rate. Other positive results were anti-cytomegalovirus, rubella virus and anti-herpes simplex virus IgG antibodies, but not IgM.

After initial evaluation, the patient was treated for non-infectious panuveitis with periocular injections of triamcinolone acetonide 40 mg in each eye. Subretinal fluid decreased quickly within two days of treatment, (Fig. 4). Blurred vision resolved in five days, and the patient has had no recurrent ocular disturbance through four months of follow-up.

Fig. 3. Ultra-widefield fluorescein angiography showing multiple hyperfluorescent spots and choroidal hyperfluorescent foci inferiorly in the late phase (right column).

Fig. 4. Follow-up optical coherence tomography of the patient after treatment with periocular steroids showing decreased subretinal fluid (lower) compared with baseline (upper).
3. Discussion

Our case highlights the possibility of panuveitis following administration of an inactivated Covid-19 vaccine. While the rapid resolution of the disease with excellent visual recovery reassured us that this type of adverse event could be transient and treatable, the mechanism underlying vaccine-associated uveitis is unclear, and it is difficult to prove causality in these rare cases. Commonly proposed mechanisms of inflammation may be induced by the adjuvants that are routinely used in inactivated or subunit vaccines to enhance the immunogenicity of the virus.12-14 The autoimmunity has been classified as Shoenfeld syndrome that is often accompanied by arthralgia and fatigue, typically occurring in patients with an autoimmune disorder. Like our case, VKH-like uveitis is reported to occur mostly in association with the inactivated vaccines against yellow fever, influenza, BCG and HPV.15-17 However, there are reported VKH diseases related to Pfizer mRNA as well as the adenovirus vector vaccine (AZD1222). Reactivation of VKH disease after the second dose of Pfizer mRNA (BNT162b2) has also been reported.18 Both of these vaccines do not utilize an additional adjuvant.19-20 Due to the similar phenotype of uveitis despite a different type of vaccine, antigen mimicry from the virus could be a potential trigger. In this case, additional aqueous humor analysis ruled out intraocular infection and demonstrated the inflammatory status, with prominent elevated IL-6. More analyses are needed to elucidate the mechanism of this reaction.

Although we called this case VKH-like uveitis due to the inflammatory nature and multiple serous detachments of the neurosensory retina, the OCT did not show features like subretinal septa or folds of the retinal pigmented epithelium as are often seen in VKH.21 The FA of this patient showed mild and even hyperfluorescence in the area of retinal detachment, unlike multifocal leaks at the level of the retinal pigment epithelium that pool into the sub-neurosensory retinal space in VKH syndrome.17,18 There are some deep focal lesions in the mid-periphery in both eyes that are consistent with the hyperfluorescent spot on the FA. However, there are no positive findings in the AF or OCT, distinguishing this condition from MEWDS.19-21 Given the atypical combined features in this case, the close temporal relationship between the symptom onset and the vaccination, the immunocompetent status of this patient, no evidence of infection, and quickly improvement in vision following treatment with steroids, the vaccine can be categorized as a probable trigger, according to the Naranjo adverse event probability scale.22 Nevertheless, a causal relationship cannot be established from this single case report.

4. Conclusions

As the urge for a vaccination against Covid-19 continues, potential ocular adverse events should be reported in detail to increase awareness among the medical community.

Patient consent

Written informed consent was obtained from the patient for publication of this case report and use of any accompanying images.
