Electrical stimulation of the hippocampal commissure with a pattern of pulses that mimics specific aspects of hippocampal physiological activity results in a long-lasting enhancement of the CA1 evoked response. We refer to this pattern-dependent increase in response as primed burst (PB) potentiation (Diamond, Dunwiddie, & Rose, 1988; Rose & Dunwiddie, 1986). The primary finding of the present study is that, in the urethane-anesthetized rat, there is a negative linear correlation between the magnitude of PB potentiation and elevated levels of serum corticosterone ($r = -0.76, p < .001$). In contrast, there was no significant relationship between the magnitude of posttetanic potentiation (PTP) and the level of serum corticosterone ($r = 0.13, p > .1$). In addition, we observed a novel form of long-term depression of the population spike amplitude (PB depression) in recordings from 4 animals that had very high levels (> 60 μg/dl) of corticosterone. The magnitudes of PTP were not different across groups that developed PB potentiation ($n = 9$), no change in response ($n = 7$), or PB depression ($n = 4$). These findings suggest that corticosterone exerts a concentration-dependent inhibitory influence on long-term, but not short-term, hippocampal plasticity in the urethane-anesthetized rat. The present findings complement previous work indicating that stress-related adrenal hormones, and corticosterone in particular, can modulate behavioral learning and hippocampal plasticity.

Adrenal-related hormones are potent modulators of both learning (Bennett, Liang, & Mcgaugh, 1985; Bohus, 1973; Borrell, de Kloet, Versteeg, & Bohus, 1983; Liang, Bennett, & Mcgaugh, 1985; Mcgaugh, 1989) and brain plasticity (Diamond, Bennett, Engstrom, Fleschner, & Rose, 1989; Dubrovsky, Liquornik, Noble, & Gijsbers, 1987; Gold, Delanoy, & Merrin, 1984). Corticosterone, the primary glucocorticoid in rodents, is released from the adrenal cortex during stress and can modulate learning (Archer, Ogren, Fuxe, Agnati, & Eneroth, 1981; Bohus, 1973; Bohus & de Kloet, 1981; Bohus, Grubits, Kovacs, & Lissak, 1970) and neural activity (Joels & de Kloet, 1989; Kerr, Campbell, Hao, & Landfield, 1989; Pfaff, Silva, & Weiss, 1971; Reiheld, Teylor, & Vardaris, 1984). The highest density of corticosterone receptors in the nervous system is found in the hippocampus (Magariños, Ferrini, & De Nicola, 1989; Reul & de Kloet, 1985), a structure that serves a critical role in memory formation (Squire, 1986; Zola-Morgan, Squire, & Amaral, 1986). Collectively, these lines of research suggest that the corticosterone modulation of hippocampal activity underlies some aspects of the effects of stress on learning and memory.
Hippocampal long-term potentiation (LTP) is a well-described physiological model of memory, in which a long-lasting enhancement in synaptic efficacy occurs in response to high-frequency electrical stimulation (Lynch, Muller, Seubert, & Larson, 1988; Teylor & DiScenna, 1987). LTP has characteristics in common with memory, such as its rapid induction and long duration. Moreover, recent work has shown that electrical stimulation patterned to mimic aspects of hippocampal physiology is maximally effective at inducing LTP (Diamond, Dunwiddie, & Rose, 1988; Greenstein, Pavlides, & Winson, 1988; Larson & Lynch, 1986; Larson, Wong, & Lynch, 1986; Pavlides, Greenstein, Grudman, & Winson, 1988; Rose & Dunwiddie, 1986). We refer to this low threshold form of LTP as primed burst (PB) potentiation (Diamond et al., 1988; Rose & Dunwiddie, 1986).

Previous studies have demonstrated that stress inhibits LTP (Foy, Stanton, Levine, & Thompson, 1987; Shors, Seib, Levine, & Thompson, 1989) and PB potentiation (Diamond, Bennett, Stevens, Wilson, & Rose, 1990), and that adrenalectomy enhances the induction of PB potentiation (Diamond et al., 1989). These findings suggest that adrenal-related hormones exert an inhibitory influence on hippocampal plasticity. In the present study, we have therefore characterized the relationship between the magnitude of hippocampal PB potentiation and the level of serum corticosterone.

METHOD

Subjects were male Sprague-Dawley rats (Harlan Laboratories, Indianapolis, IN) weighing 275-420 g at the time of recording. The animals were group housed (2-3/cage) and given food and water ad lib. All animals had at least 1 week to acclimate to the vivarium 12:12-h light:dark cycle (lights on at 0600) before undergoing any surgical procedures. Adrenalectomy (ADX) was performed on secobarbital (40 mg/kg, i.p.) anesthetized rats 7-10 days before recording sessions took place. ADX subjects were maintained on rat chow and 9.9% saline available ad lib. At 0900-1000 on the day of recording, atropine methyl nitrate was administered (0.2 mg/kg, i.p.), followed by urethane (range: 1.1-1.5 g/kg, i.p.). Blood was obtained from the tail approximately 35 min after the induction of anesthesia; a second sample was obtained at the termination of the recording session, approximately 3.5 h later. The blood samples were analyzed for corticosterone by using a modification of radioimmunoassay (RIA) procedures (Keith, Winslow, & Reynolds, 1978), which had an intra-assay coefficient of variation of 8.7%. Serum corticosterone levels are accurately assessed by using a modification of radioimmunoassay (RIA) procedures (Keith, Winslow, & Reynolds, 1978), which had an intra-assay coefficient of variation of 8.7%. Serum corticosterone levels are accurately assessed by using a modification of radioimmunoassay (RIA) procedures (Keith, Winslow, & Reynolds, 1978), which had an intra-assay coefficient of variation of 8.7%.

When the subject was anesthetized, an incision was made and the tissue was bathed with a local anesthetic (0.4% Xylocaine). The recording electrode (etched epoxyite-insulated tungsten, impedance 0.5-1.0 MΩ at 1 kHz) was lowered to the CA1 pyramidal cell layer, which was identified by complex spike activity occurring 1.8-2.3 mm below brain surface. The stimulating electrode (125-μm-diameter stainless steel Teflon-coated wire, uninsulated at the tip) was lowered into the left side of the hippocampal commissure (coordinates AP = 1.8, ML 1.0). The final coordinates were determined by optimizing the amplitude of the population spike, which is a measure of the synchronic firing of CA1 cell activity (Andersen, Bliss, & Skrede, 1971).

Stimulus-evoked responses were displayed on an oscilloscope and stored in an Epson computer for on- and off-line analysis. Test responses were evoked by constant-current single-pulse stimuli (150-μsec duration) presented every 30 sec for 10 min before and 20 min following PB stimulation. PB stimulation consisted of a single pulse, followed 170 μsec later by a burst of 4 pulses at 200 Hz. PB stimulation current levels were 150% of the current levels used in test pulses. Statistical analysis (t test) of the changes in the population spike amplitude was performed for each subject by comparing responses obtained during the 5-min period immediately prior to PB stimulation with those obtained during the 1- to 2-min (posttetanic potentiation, or PTP) and 16- to 20-min (PB potentiation) periods after PB stimulation. Statistical comparisons across groups of animals were performed with a multivariate analysis of variance (MANOVA). Data are presented as the mean (±SEM) unless otherwise noted. Additional details concerning the methodology are provided in Diamond et al. (1989).

RESULTS

Physiological recordings and serum corticosterone analyses were performed on 20 adrenal-intact (intact) and 12 adrenalectomized (ADX) subjects. The intact subjects had serum concentrations of corticosterone in the stress range (25-93 μg/dl, M = 53.4 ±4.1 μg/dl). This finding is consistent with previous studies demonstrating that urethane anesthesia produces a chronic elevation of corticosterone levels (Dunn, 1987; Hamstra, Doray, & Dunn, 1984; Spriggs & Stockham, 1964) through the increased release of ACTH (Ondo & Kitay, 1973). The mean corticosterone level in ADX subjects was 1.4 μg/dl (±0.3). Levels of corticosterone in this low range are commonly measured in adrenalectomized rats, presumably from extra-adrenal tissue producing small quantities of corticosterone (Roy, Lynn, & Bemm, 1990). The baseline stimulation current was 59.4 μA (±9.3) for the ADX group and 49.0 μA (±4.9) for the intact group. The baseline population spike amplitude was 2.56 mV (±0.30) for the ADX group and 2.32 mV (±0.25) for the intact group.

There was a significant negative correlation between the magnitude of PB potentiation and level of serum corticosterone in intact animals (r = -.76, p < .001; see Figure 1). Intact subjects exhibited a significant increase (n = 9), no change (n = 7), or a decrease (n = 4) in the amplitude of the population spike in the 16- to 20-min period following PB stimulation (paired t test). The magnitudes of the evoked responses in this time period were significantly different across the three groups [increase, 82.5% ±12.1%; no change, 1.7% ±11.0%; decrease, -42.8% ±10.9%; repeated measures MANOVA, F(2,17)
Possible Basis of the Negative Correlation Between Corticosterone and PB Potentiation

As in our previous work, both the incidence and the magnitude of PB potentiation were greater in adenalec­
tomized than in intact rats (Diamond et al., 1989). The present work extends our initial findings by describing a systematic relationship between PB potentiation and corticosterone. Specifically, there was a negative linear correlation between the magnitude of PB potentiation and the level of serum corticosterone. In addition, we have shown that serum corticosterone level is correlated with the mag­nitude of long-term, but not short-term, plasticity, and that PB stimulation induced a decrease in the amplitude of the population spike in animals with the highest levels of corticosterone measured.

Figure 2. Heterogeneous long-term, but not short-term, responses produced by primed burst (PB) stimulation. PB stimulation was del­ivered at Time 0 (−5 to −1 min is baseline stimulation, and 1–20 min is the post-PB stimulation period). PB stimulation induced an increase in response in 9 animals (open square) and a decrease in response in 4 animals (filled circle). No significant change in response occurred in 7 animals (data points identified with an x). Data are expressed as the mean (±SE) for 1-min values. Error bars for most of the no-change group data points are within the size of the data points.
Our finding of a negative correlation between stress levels of corticosterone and PB potentiation is consistent with recent work indicating that corticosterone can affect the excitability of hippocampal neurons through the activation of two types of receptors, referred to as Type I and Type II glucocorticoid receptors. The Type I receptor, which has a high affinity for corticosterone, is located primarily in the hippocampus, but the Type II receptor, which has a lower affinity for corticosterone, is widely distributed throughout the nervous system (Magariños et al., 1989; Reul, van den Bosch, & de Kloet, 1987). Type I receptors become saturated at relatively low levels of corticosterone (less than 20 μg/dl), but Type II receptors bind corticosterone in the range of approximately 20-100 μg/dl (de Kloet & Reul, 1987; Spencer, Young, Choo, & McEwen, 1990). It is likely that Type I receptors were saturated in all of the recordings from adrenal-intact rats in the present study, while there was a concentration-dependent occupation of the Type II receptors.

Activation of the Type II receptor by corticosterone increases the amplitude of a long-duration inhibitory potential, referred to as the afterhyperpolarization (AHP) (Joels & de Kloet, 1989, 1990; Kerr et al., 1989). The priming pulse of PB stimulation produces an AHP (Storm, 1987). It is therefore likely that in recordings from rats with increased levels of corticosterone there was an increased magnitude of the AHP that may have damped the level of depolarization produced by the four-pulse burst (Davies, Starkey, Pozza, & Collingridge, 1991; Pacelli, Su, & Kelso, 1989). This putative blockade of depolarization by corticosterone may have interfered with the NMDA-mediated induction of PB potentiation (Diamond et al., 1988; Larson & Lynch, 1988). We suggest that the basis of the negative correlation between corticosterone and PB potentiation is an increase in AHP amplitude produced by the concentration-dependent occupation of Type II receptors.

**PB Depression**

In 20% of the recordings, PB stimulation induced a significant decrease in the amplitude of the CA1 population spike. We refer to this decrease in response as PB depression. We considered the possibility that PB depression occurred as a result of seizure activity. However, we did not observe physiological indicators of seizure activity in any recordings. This finding is consistent with other work which shows that urethane anesthesia raises the threshold for the development of seizure activity (Cain, Raithby, & Corcoran, 1989). Moreover, seizure activity would have been expected to produce an initial short-term depression of activity followed by either a return of the amplitude of the response to baseline levels or a potentiation of the response (Buzsaki, 1980; Staubli & Lynch, 1987). Instead, recordings of PB depression showed an initial increase in response followed by a long-lasting...
decrease in response. Therefore, PB depression was not likely to have been produced as a result of seizure-related activity.

The characteristics of the PB depression described in this study are consistent with a mechanism of long-term depression (LTD) proposed by Artola, Brocher, and Singer (1990). Their work, in concert with similar findings of Stanton and Sejnowski’s (1989), indicates that the depolarization threshold for LTD is lower than that for LTP. They also demonstrated that identical parameters of electrical stimulation can induce either LTD or LTP, depending on the level of postsynaptic depolarization at the time of high-frequency stimulation. Without exception, the subjects that exhibited PB depression had very high levels of serum corticosterone (greater than 60 µg/dl). It is possible that the amplitude of the AHP associated with these high levels of corticosterone damped the burst-induced depolarization such that the threshold for PB depression, but not PB potentiation, was exceeded.

One approach toward a greater understanding of the mechanisms underlying PB depression is to administer selective Type II agonists and then deliver PB stimulation. We predict that there will be a negative relationship between the magnitude of PB potentiation and the concentration of a Type II agonist, such as dexamethasone. We would also expect that a negative correlation between dexamethasone and PB potentiation would produce PB depression at sufficiently high concentrations of dexamethasone.

**Discrepancy Between Predicted and Empirically Determined Data**

The recordings in the present study were limited to relatively high serum corticosterone levels that corresponded to stress levels of corticosterone in the awake animal. The shape of the corticosterone/PB potentiation function for corticosterone levels below 25 µg/dl remains to be determined. An extrapolation of the linear regression shown in Figure 1 predicts that the amplitude of PB potentiation would be approximately a 175% increase in response at the trace levels of corticosterone found in the ADX subjects. Instead, we found an increase of only 73% in the ADX subjects. Moreover, there was no overlap between the mean and the standard error of PB potentiation for the ADX group and the 95% confidence limits of the regression line at the y intercept.

One possible explanation for the discrepancy is that corticosterone produces an inverted-U-shaped modulation of hippocampal plasticity. According to this hypothesis, PB potentiation reaches a peak magnitude at an intermediate level of corticosterone (e.g., 10–20 µg/dl) and then declines as corticosterone levels approach 0 µg/dl. An inverted-U relationship between an adrenal hormone and hippocampal plasticity has been described previously by Gold et al. (1984). These investigators demonstrated that there is an inverted-U relationship between the dose of peripherally administered epinephrine and the magnitude of hippocampal LTP in anesthetized rats. Inverted-U relationships between stress hormones and hippocampal plasticity may underlie the well-described inverted-U modulation of learning by arousal (Broadbent, 1971; Broadhurst, 1959; Lundberg, 1982; Yerkes & Dodson, 1908).

An alternative hypothesis is that the discrepancy is the result of ADX-induced sequelae (see, e.g., de Kloet, Sybesma, & Reul, 1986; Miller, Greenblatt, Barnhill, Thompson, & Shader, 1988; Swann, 1988). This hypothesis predicts that intact animals with low levels of corticosterone (1–2 µg/dl) will have a PB potentiation magnitude of approximately 175% (the linear regression y intercept value). If this does occur, the discrepancy between the expected and observed values in the present study would appear to be a result of an adrenalectomy-induced uncoupling of the hormonal modulation of hippocampal plasticity.

Our initial studies to distinguish between these two alternatives support the inverted-U hypothesis. In animals that have experimenter-determined levels of corticosterone (by means of adrenalectomy and the implantation of corticosterone pellets), the corticosterone/PB potentiation curve reaches a peak PB potentiation magnitude at approximately 9–20 µg/dl, with a reduction in the magnitude of PB potentiation in animals with lower and higher levels of corticosterone (Diamond, Bennett, Meltzer, Fleshner, & Rose, 1991).

**Relation to Previous Studies**

The negative correlation between corticosterone and PB potentiation does not appear to be produced as an artifact of the urethane anesthesia, nor is it induced only by primed burst stimulation. A similar negative correlation between hippocampal plasticity and corticosterone was reported by Foy et al. (1987), whose methodology differed considerably from that in the present work. Foy et al. applied a high-frequency train of 100 pulses to the hippocampal slice obtained from unanesthetized, stressed rats. In contrast, we applied a total of 5 physiologically patterned pulses to the intact hippocampus of urethane-anesthetized rats. Hence, the correlation between hippocampal long-term plasticity and corticosterone appears to be a robust phenomenon that is expressed (1) in response to physiologically patterned stimulation or more conventional LTP stimulation, (2) in the presence or absence of anesthesia, and (3) in CA1 of either the intact hippocampus in vivo or the hippocampus in vitro.

The similarity between our observations of the modulation of hippocampal plasticity and those of Foy et al. (1987) parallels observations of the effects of stress on long-term plasticity in unanesthetized rats. We have shown that stress interferes with the development of PB potentiation in behaving rats (Diamond et al., 1990). Similarly, Thompson and his colleagues have demonstrated that stress blocks the induction of LTP (Foy et al., 1987; Shors et al., 1989). However, there is less consistency in the effects of stress on short-term plasticity. We have shown that stress completely blocked the induction of PTP in recordings from behaving rats (Diamond et al., 1990).
In contrast, Shors et al. (1989) observed an attenuation of PTP by stress, whereas in other work from their laboratory there was no effect of stress on PTP (Foy et al., 1987; Shors, Levine, & Thompson, 1990).

In the present study, PTP occurred in all animals, independently of corticosterone level. These contrasts between stress and corticosterone effects on PTP and LTP are consistent with the hypothesis that long- and short-term forms of plasticity are induced by different mechanisms (McNaughton, 1982). They also indicate that stress in the behaving animal can produce a potent blockade on short- and long-term forms of plasticity, but a pharmacologically induced increase in corticosterone, as described here, is associated only with the suppression of long-term plasticity. The finding that serum corticosterone in the anesthetized rat does not affect PTP is consistent with the evidence that substances other than corticosterone, such as opioids (Shors, Levin, & Thompson, 1990), contribute to stress effects on hippocampal plasticity.

Summary
We have demonstrated that there is an inverse relationship between levels of corticosterone and the magnitude of PB potentiation. Although these data are correlative, they are consistent with the possibility of a direct modulation of hippocampal plasticity by corticosterone.
