(Dated: September 27, 2018)

While Flory theories [1–5] provide an extremely useful framework for understanding the behavior of interacting, randomly branching polymers, the approach is inherently limited. Here we use a combination of scaling arguments and computer simulations to go beyond a Gaussian description. We analyse distribution functions for a wide variety of quantities characterising the tree connectivities and conformations for the four different statistical ensembles, which we have studied numerically in Refs. [6, 7]: (a) ideal randomly branching polymers, (b) 2d and 3d melts of interacting randomly branching polymers, (c) 3d self-avoiding trees with annealed connectivity and (d) 3d self-avoiding trees with quenched ideal connectivity. In particular, we investigate the distributions (i) \( p_N(n) \) of the weight, \( n \), of branches cut from trees of mass \( N \) by severing randomly chosen bonds; (ii) \( p_{N}(l) \) of the contour distances, \( l \), between monomers; (iii) \( p_N(r) \) of spatial distances, \( r \), between monomers, and (iv) \( p_{N}(\vec{r}/l) \) of the end-to-end distance of paths of length \( l \). Data for different tree sizes superimpose, when expressed as functions of suitably rescaled observables \( \vec{x} = r/l(\nu^2(N)) \) or \( x = l/(l(N)) \). In particular, we observe a generalised Kramers relation for the branch weight distributions (i) and find that all the other distributions (ii-iv) are of Redner-des Cloizeaux type, 

\[ q(x) = C|x|^{-\nu} \exp(-K|x|) \]

We propose a coherent framework, including generalised Fisher-Pincus relations, relating most of the RdIC exponents to each other and to the contact and Flory exponents for interacting trees.

I. INTRODUCTION

A randomly branched tree is a finite connected set of bonds that contain no closed loops and which is embedded in a \( d \) dimensional space. Aside from their importance in statistical physics [8] and the intriguing connection to relevant physical problems as percolation [9], randomly branched trees have received particular attention for being practically implicated in the modelling of branched [10], ring [4, 11–16] and supercoiled [17] polymers.

As customary in polymer physics [10, 18], the behavior of randomly branched trees can be analyzed in terms of a small set of exponents describing how expectation values for observables characterising tree connectivities and conformations vary with the weight, \( N \), of the trees or the contour distance, \( L \), between nodes:

\[
\begin{align*}
\langle N_{\text{br}}(N) \rangle &\sim N^\epsilon \\
\langle (L)(N) \rangle &\sim N^\rho \\
\langle R^2(L) \rangle &\sim L^{2\nu_{\text{path}}} \\
\langle R^2_{g}(N) \rangle &\sim N^{2\nu} \\
\langle N_{c}(N) \rangle &\sim N^{\gamma_{c}} \\
\langle N_{\text{inter}}(N) \rangle &\sim N^{\beta}
\end{align*}
\]

(1) (2) (3) (4) (5) (6)

Here, \( \langle N_{\text{br}}(N) \rangle \) denotes the average branch weight; \( \langle L(N) \rangle \) the average contour distance or length of paths on the tree; \( \langle R^2(L) \rangle \) the mean-square spatial distance between nodes with fixed contour distance; \( \langle R^2_{g}(N) \rangle \) the mean-square gyration radius of the trees; \( \langle N_{c}(N) \rangle \) the average number of intra-tree pair contacts; \( \langle N_{\text{inter}}(N) \rangle \) the average number of pair contacts between different trees in melt.

Exact values for the exponents are known only for a very few number of cases. For ideal non-interacting trees, the exponents \( \nu_{\text{ideal}} = \nu = \nu_{\text{path}} = 1/2 \) and \( \epsilon_{\text{ideal}} = 1/4 \) [20, 21]. Furthermore, \( \gamma_{c} = 2 - d\nu_{\text{ideal}} \) where \( d \) denotes the dimension of the embedding space. For interacting trees, the only known exact result [22] is the value \( \nu = 1/2 \) for self-avoiding trees in \( d = 3 \). On the other hand, numerical results [3, 7, 13, 22] as well as approximate theoretical calculations [24, 25] confirm that Flory theories [1–5] provide a useful framework for discussing the average behavior, Eqs. (1) to (6), of a wide range of interacting tree systems. While being remarkably successful though, due to its simplicity Flory theory is inevitably affected by serious known shortcomings and limitations [26, 27]. They are, for instance, manifest in (small) deviations of predicted from observed or exactly known values for exponents as those defined in Eqs. (1) to (6), and, importantly, it does not give any insight for the equally relevant exponent \( \beta \), Eq. (6). In the case of linear chains, these limitations are much more pronounced in the distribution functions for the corresponding observables which contain a wealth of additional information.

Little seems to be known about the even larger range...
II. THEORETICAL BACKGROUND

A. Ideal trees

Consider a tree of mass \(N\) defined as \(N + 1\) monomers connected by \(N\) bonds or Kuhn segments. For ideal trees, Daoud and Joanny \cite{2} calculated the partition function \(Z_N\) in the continuum approximation:

\[
Z_N = \frac{I_1(2\lambda N)}{\lambda N} \approx \begin{cases} 
\frac{2^{2N}}{2\pi^{1/2}(\lambda N)^{3/2}}, & \lambda N \gg 1 \\
1 + \frac{(\lambda N)^2}{2}, & \lambda N \ll 1 
\end{cases}
\]  

(7)

where \(I_1(x)\) is the first modified Bessel function of the first kind, \(\lambda\) the branching fugacity and \(Z_0 = 1\). Removing a randomly chosen bond, splits a branch of size \(n < N/2\) from the remaining tree of size \(N - n - 1\). For ideal trees, the probability distribution, \(p_N(n)\), of branch sizes is given by the Kramers theorem \cite{10}:

\[
p_N(n) = \frac{Z_n Z_{N-1-n}}{\sum_{n=0}^{N-1} Z_n Z_{N-1-n}},
\]  

(8)

and related to sum over all possible ways of splitting the tree. From this expression, it is possible to derive the following asymptotic relations:

\[
p_N(n) \approx \begin{cases} 
\frac{\lambda(N)^{3/2}}{4\pi^{1/2}(\lambda N)^{3/2}(\lambda(N-n-1)^{3/2})}, & \lambda n \gg 1 \\
\frac{\lambda}{4\pi^{1/2}(\lambda N)^{3/2}}, & \lambda N \gg \lambda n \gg 1 \\
\frac{1}{N}, & \lambda N \ll 1 
\end{cases}
\]  

(9)

with \((N_{br}(N)) \sim N^{1/2} = N^{2-x}\), where \(x = 3/2\) is the scaling exponent describing the decay of \(p_N(n)\) in the large-\(N\) limit, Eq. (9).

B. Flory theory of interacting trees

Flory theories are formulated as a balance of an entropic elastic term and an interaction energy \cite{28}:

\[
\mathcal{F} = \mathcal{F}_{el}(N, R) + \mathcal{F}_{inter}(N, R).
\]  

(10)

In the standard case of self-avoiding walks, \(\frac{\mathcal{F}_{el}(N,R)}{k_BT}\) represents the entropic elasticity of a linear chain, while \(\frac{\mathcal{F}_{inter}(N,R)}{k_BT}\) represents the two-body repulsion between segments, which dominates in good solvent. For interacting trees, the elastic free energy takes the form \cite{3}:

\[
\frac{\mathcal{F}_{el}}{k_BT} \sim \frac{R^2}{l_K L} + \frac{L^2}{Nl_K^2}.
\]  

(11)

The expression reduces to the entropic elasticity of a linear chain for unbranched trees with quenched \(L = l_K N\). The first term of Eq. (11) is the usual elastic energy contribution for stretching a polymer of linear contour length \(L\) at its ends \cite{2}. The second term penalises deviations from the ideal branching statistics, which lead to longer paths and hence spatially more extended trees. More formally, it is calculated from the partition function of an ideal branched polymer of \(N\) bonds with \(L\) bonds between two arbitrary fixed ends \cite{3, 21, 29}. For trees with quenched connectivity, Eq. (11) has to be evaluated for the given mean path length \(L\) and then minimised with respect to \(R\). For trees with annealed connectivity, Eq. (11) needs to be minimised with respect to both, \(R\) and \(L\).

In this form, the theory predicts values for the exponents \(\nu, \rho, \nu_{path}\) for a wide range of tree systems \cite{3, 7} as a function of the embedding dimension, \(d\), as well as relations between these exponents. For example, optimising \(L\) for annealed trees for a given asymptotic, \(R \sim N^{\nu}\), yields

\[
\rho = \frac{1 + 2\nu}{3}
\]  

(12)

\[
\nu_{path} = \frac{3\nu}{1 + 2\nu}
\]  

(13)

independently of the type of volume interactions causing the swelling in the first place. Plausibly, a fully extended system, \(\nu = 1\), is predicted not to branch, \(\rho = 1\), and to have a fully stretched stem, \(\nu_{path} = \nu = 1\). For the radius of ideal randomly branched polymers, \(\nu = 1/4\), one recovers \(\rho = 1/2\) and Gaussian path statistics, \(\nu_{path} = 1/2\).
C. Linear chains beyond Flory theory

There is more to (linear) polymers than can be described by Flory theory. The number of self-avoiding walks is given by

$$Z_{SAW}(N) \sim \mu^N N^{\gamma-1}$$  \hspace{1cm} (14)

with a universal exponent $\gamma$ and a non-universal constant $\mu$ characteristic of the employed lattice. Flory theory can neither predict the functional form of Eq. (14), nor the numerical value of $\gamma$, nor the related contact probability \cite{27, 30}

$$p_c \sim N^{-\nu(d+\theta)}$$  \hspace{1cm} (15)

$$\theta = \frac{\gamma - 1}{\nu}.$$  \hspace{1cm} (16)

Furthermore, Flory theory incorrectly predicts that stretched chains exhibit essentially Gaussian behavior with volume interactions becoming quickly negligible. Instead, the end-to-end distance distribution of self-avoiding walks is given by \cite{27, 30} distribution $p_c$ and (2) that the second moment was chosen as the scaling similarly to Eq. (14):

$$Z = \int \cdots \int d\vec{x} q(\vec{x})$$

$$q(\vec{x}) = C x^\theta \exp \left( - K x^D \right)$$  \hspace{1cm} (18)

with $q(\vec{x})$ independent of $N$. For small distances, Eq. (18) is dominated by the power law with the exponent $\theta$ given by the contact exponent Eq. (15). For large distances, the chain behaves like a string of $N/g$ blobs of size $\xi \sim g^\nu$. For a given extension $r/\xi$, the free energy of $k_B T$ per blob implies that the exponents $t$ is given by \cite{32, 34}

$$t = \frac{1}{1 - \nu}.$$  \hspace{1cm} (19)

Interestingly, knowledge of the two exponents is sufficient to reconstruct the entire distribution function, because the constants $C$ and $K$ are determined by the conditions (1) that the distribution is normalized ($\int q(\vec{x})d\vec{x} \equiv 1$) and (2) that the second moment was chosen as the scaling length ($\int |x|^2 q(\vec{x})d\vec{x} \equiv 1$):

$$C = \frac{\Gamma(1 + \frac{\theta}{d})\Gamma \left(\frac{d + \theta}{2} + \frac{\theta}{d} \right)}{\pi^{d/2} \Gamma \left(\frac{d + \theta}{2} \right)}$$

$$K^2 = \frac{\Gamma \left(\frac{2 + \theta}{2} \right)}{\Gamma \left(\frac{\theta}{2} \right)}.$$  \hspace{1cm} (20)

D. Lee-Yang edge singularity

Lattice trees are believed to fall into the same universality class as lattice animals \cite{35, 37} with their number scaling similarly to Eq. (14):

$$Z_{SAT}(N) \sim \mu^N N^{\gamma-1}$$  \hspace{1cm} (22)

In particular, the tree and animal critical exponents in $d$-dimensions are related to the Lee-Yang edge singularity \cite{22, 38, 40} of the Ising model in an imaginary magnetic field in $(d-2)$-dimensions, suggesting a relation between the entropy and the size

$$\gamma(d) = -\nu(d)(d-2).$$  \hspace{1cm} (23)

Interestingly, this relation suggests that it is possible to estimate the number of self-avoiding trees using Flory theory.

III. MODEL AND METHODS

In this section, we account very briefly for the algorithms used for generating equilibrated configurations of trees (Sec. III A) and the numerical schemes employed for their analysis (Sec. III B). The reader interested in more technical details may look into our former works \cite{4, 7}. A longer discussion is dedicated to how we extracted and extrapolated scaling exponents for RdC functions and contacts (Sec. III C). Quantitative details as well as tabulated values for single-tree statistics are presented in the Supplemental Material.

A. Generation of equilibrated tree configurations for different ensembles

To simulate randomly branching polymers with annealed connectivity, we employ a slightly modified version of the “amoeba” Monte-Carlo algorithm \cite{32} for trees on the cubic lattice with periodic boundary conditions. In the model, connected nodes occupy adjacent lattice sites. As there is no bending energy term, the lattice constant equals the Kuhn length, $l_K$, of linear paths across ideal trees. The functionality of nodes is restricted to the values $f = 1$ (a leaf or branch tip), $f = 2$ (linear chain section), and $f = 3$ (branch point). We have studied ideal non-interacting trees, 3d self-avoiding trees, and 2d and 3d melts of trees.

In addition, we have studied randomly branched trees with quenched ideal connectivity. For this ensemble, we have resorted to an equivalent off-lattice bead-spring model and studied it via Molecular Dynamics simulations. In this model, trees are represented by the same number of degrees of freedom, with bonds described as harmonic springs of average length equal to $l_K$. This allows a one-to-one mapping to and from the lattice model. Furthermore, beads interact with a repulsive soft potential whose strength is tuned in such a way, that the gyration radii of self-avoiding lattice trees remain invariant under the switch to the off-lattice model, if their quenched connectivities are drawn from the ensemble of self-avoiding on-lattice trees with annealed connectivity.

For all our ensembles, the tree sizes are $3 \leq N \leq 1800$ for ideal and self-avoiding trees \cite{4} and $3 \leq N \leq 900$ for melts of trees \cite{7}.
B. Analysis of tree connectivity

We have analysed tree connectivities using a variant of the “burning” algorithm for percolation clusters \([41, 42]\). The algorithm works iteratively: each step consists in removing from the list of all nodes the ones with functionality = 1 and updating the functionalities and the indices of the remaining ones accordingly. The algorithm stops when only one node (the “center” of the tree) remains in the list. In this way, by keeping track of the nodes which have been removed it is possible to obtain information about the mass and shape of branches. The algorithm can be then generalized to detect the minimal nodes which have been removed it is possible to obtain indices of the remaining ones accordingly. The algorithm removing from the list of all nodes the ones with function 

\[ \Delta = \Delta_0. \]

We have carried out a one-dimensional search for the value of \(\Delta_0\) for which the fits yield vanishing \(N^{-\Delta_0} \log N\) term. Note that we have analyzed data for \(\theta_l\) (and \(t_l\)) in Eq. (24) in the form “\(\log \theta_l\) vs. \(\log N\)” (log-log), while for \(\theta_{\text{tree}}\) (and \(t_{\text{tree}}\)) we have used in Eq. (25) data in a log-linear representation, “\(\theta_{\text{tree}}\) vs. \(\log N\).” These two different functional forms have been found to produce the best (statistical significant) fits.

2. In the second method we fixed \(\Delta = 1\), and we calculated the corresponding 2-parameter best fits to the same data.

Results from the two fits are summarized separately in Tables SI and SIII and their averages taken for our final estimates of scaling exponents (see the corresponding boldfaced numbers). In the tables, we have also reported which ranges of \(N\) have been considered for the best fits to the data. Unfortunately, for \(\theta_{\text{path}}\) and \(t_{\text{path}}\) an analogous scheme cannot be applied because we have data only for very limited ranges of \(l\). Then, our best estimates come from simply averaging single values together (see boldfaced numbers in Table SII).

C. Finite-size effects

As discussed in detail in our former works \([4, 7]\), extrapolation to the large-\(N\) limit of scaling exponents is a delicate issue. In general, in fact, our data are affected by finite-size effects and extracted exponents are either (i) effective (crossover) exponents valid for the particular systems and system sizes we have studied or (ii) estimates of true, asymptotic exponents, which suffer from uncertainties related to the extrapolation to the asymptotic limit.

Extrapolating scaling exponents of distribution functions – Pairs of exponents \((\theta_l, t_l)\), \((\theta_{\text{path}}, t_{\text{path}})\), and \((\theta_{\text{tree}}, t_{\text{tree}})\) are obtained by best fits of data for distribution functions \(p_N(l)\), \(p_N(r_l|l)\) and \(p_N(r)\) to the corresponding 2-parameter Redner-des Cloizeaux functions (Eqs. (28), (44) and (67), respectively). As shown in Tables SI-III the values obtained from these fits display non negligible finite-size effects. Then, the search for extrapolated values has required two separate strategies. For exponents \((\theta_l, t_l)\) and \((\theta_{\text{tree}}, t_{\text{tree}})\), we follow a procedure similar to the one outlined first in \([19]\) and adopted later by us in \([4, 7]\). It combines together the two following extrapolation schemes:

1. A fit of the data for \(\theta_l\) and \(\theta_{\text{tree}}\) to the following 3-parameter fit functions:

\[
\log \theta_l = a + b N^{-\Delta_0} - b(\Delta - \Delta_0) N^{-\Delta_0} \log N
\]
\[
\equiv a + b e^{-\Delta_0 \log N} - b(\Delta - \Delta_0) e^{-\Delta_0 \log N} \log N
\]

(24)

and

\[
\theta_{\text{tree}} = a + b N^{-\Delta_0} - b(\Delta - \Delta_0) N^{-\Delta_0} \log N
\]
\[
\equiv a + b e^{-\Delta_0 \log N} - b(\Delta - \Delta_0) e^{-\Delta_0 \log N} \log N
\]

(25)

and analogous expressions for \(t_l\) and \(t_{\text{tree}}\). Eqs. (24) and (25) correspond to a self-consistent linearisation of the 3 parameter fit \(\theta_l, t_l,\) around

IV. RESULTS AND DISCUSSION

We begin with distribution functions for observables characterizing the tree connectivity: the distribution of branch weights (Sec. IV A) and path lengths (Sec. IV B). Then, we turn to the conformational statistics of linear
path on the tree (Sec. IV C) and the distribution of internal distances (Sec. IV D).

A. Branch weight statistics and generalised Kramers relation

In Figure 1 we show the distribution, $p_N(n)$, of the weight, $n$, of the branches generated by cutting randomly selected bonds in trees of size $N$. Obviously, it is possible to cut larger branches from larger trees, but independently of $N$ the vast majority of the branches is small.

This follows immediately from the fact that for all our systems a large fraction ($\approx 40\%$) for ideal and melt of trees and $\approx 27\%$ for annealed self-avoiding trees (Fig. 2) of the nodes is one-functional: cutting the bonds joining them to the tree generates branches of weight $n = 0$.

To gain some intuition for the form of these distributions, it is useful to reconsider the case of ideal trees (Section IV, Eqs. 27, 30), where $Z_n \sim e^{2Nn/(\lambda n)^{3/2}}$. In that case, $p_N(n) \sim n^{-3/2}$ for small $1 < n < N$. As expected, by plotting data for $p_N(n)$ in log-log plots as a function of $n$ (l.h. column of Fig. 1) we find good agreement with the expected power law for small $n$, while plotting data as a function of $n(N - 1 - n)$ (r.h.s) produces nearly perfect power law behavior over the entire range $1 \leq n \leq N/2$.

Interestingly, we find similar power law behaviour for interacting trees, too. We therefore tentatively generalize Eq. 7 for the tree partition function to

$$Z_n \sim e^{cn^{-x}}.$$  \hspace{1cm} (26)

In fact, this form is compatible with the Kramers theorem, Eq. 5, since $\sum_{n=0}^{N-1} Z_n Z_{N-1-n} = e^N \sum_{n=0}^{N-1} n^{-x}(N - 1 - n)^{-x} \sim c^n N^{-x} = Z_N$. The resulting average branch weight of $\langle N_{br}(N) \rangle \sim N^{2-x}$ implies $x = 2 - \epsilon$. As shown in the corresponding insets, the relation $x = 2 - \epsilon$ is well satisfied with values for $\epsilon$ taken from Refs. [6, 7]. The numerical prefactor $c$ is related to the asymptotic branching probability (see Fig. 4 in Ref. [6] and Fig. 3 in Ref. [7]), since in the limit $N \rightarrow \infty$, $\langle n_3 \rangle / N = \langle n_1 \rangle / N = 2p_N(n = 0)$ [6], and $p_N(n = 0) = Z_{N-1}/Z_N = c^{-1}(\frac{1}{Z_N})^{\frac{3}{2}} \simeq c^{-\frac{1}{2}}$.

B. Path length statistics for trees

As illustrated in Fig. 2, the measured path length distribution functions, $p_N(l)$, fall onto universal master curves, when plotted as a function of the rescaled path length $x = l/l(L(N))$:

$$p_N(l) = \frac{1}{\langle L(N) \rangle} q\left(\frac{l}{\langle L(N) \rangle}\right).$$  \hspace{1cm} (27)

These master curves are well described by the one-dimensional Redner-des Cloizeaux (RdC) form (orange lines in Fig. 2):

$$q(x) = C_l x^{\theta_l} \exp\left(-\left(K_l x^{\theta_l}\right)\right).$$  \hspace{1cm} (28)

The constants

$$C_l = t_l \frac{\Gamma(\theta_l + 1)/t_l}{\Gamma(\theta_l + 2)/t_l},$$  \hspace{1cm} (29)

$$K_l = \frac{\Gamma(\theta_l + 2)/t_l}{\Gamma(\theta_l + 1)/t_l}$$  \hspace{1cm} (30)

follow from the conditions that $p_N(l)$ is normalized to 1 and that the first moment, $\langle L(N) \rangle$, is the only relevant
Self-avoiding trees, quenched ideal connectivity.

FIG. 2: Probability distribution functions, \( p_N(l) \), for linear paths of length \( l \) and average size \( \langle L(N) \rangle \) in trees of total mass \( N \). Orange solid lines correspond to the one-dimensional Redner-des Cloizeaux function, Eq. (28), with parameters \( \theta_I \) and \( l_I \) obtained from the best fits to data for \( N = 1800 \) (ideal and self-avoiding trees) and \( N = 900 \) (2d and 3d melt of trees), see Table SI for detailed values of fit parameters. Inset: Same plots in log-log scale.

scaling variable. Estimated values for \((\theta_I, l_I)\) obtained from best fits of Eq. (28) to data for specific values of \( N \) and extrapolated values to large \( N \) are summarized in Table SI.

Interestingly, we can give a physical interpretation of the observed (effective) exponents. For small path lengths, results are not affected by the total tree size. We thus expect to find \( n(l_{\text{max}}) \sim l_{\text{max}}^{1/\rho} \) segments at a contour distance \( l \leq l_{\text{max}} \) from any node. Since \( p(l_{\text{max}}) \sim dn(l_{\text{max}})/dl_{\text{max}} \), this suggests the scaling relationship

\[
\theta_I = \frac{1}{\rho} - 1 .
\]

To estimate the probability for observing very long paths, it is tempting to adjust the Pincus-blob argument [34] cited in the Section II C. A stretched tree should behave like a string of \( N/g \) unperturbed trees of size \( \xi \sim g^\rho \), suggesting that

\[
t_I = \frac{1}{1 - \rho} .
\]

The argument works well (see bottom panel of Table I for columns (a) and (b)) when comparing the asymptotic values for \( t_I \) in different ensembles to the corresponding numerical values for \( \rho \) taken from [6, 7]. Interestingly, being only functions of \( \rho, \theta_I \) and \( t_I \) can also be explicitly calculated in terms of results for \( \rho \) from the Flory theory [6, 7], see top panel of Table I. Interestingly, the Flory theory gives a remarkable accurate prediction for most of the cases discussed.

C. Conformational statistics of linear paths

Fig. 3 shows measured end-to-end vector distributions, \( p_N(\vec{r}|l) \), for paths of length \( l \) on trees of mass \( N \). The data superimpose, when expressed as functions of the scaled distances, \( x = |\vec{r}|/\sqrt{\langle R^2(l, N) \rangle} \):

\[
p_N(\vec{r}|l) = \frac{1}{(\langle R^2(l, N) \rangle)^{3/2}} q \left( \frac{|\vec{r}|}{\sqrt{\langle R^2(l, N) \rangle}} \right) .
\]

Moreover, they are in excellent agreement with the RdC distribution (Eqs. 18, 20 and 24) and orange lines in Fig. 3:

\[
q(x) = C x^{\theta_\text{path}} \exp \left( -(Kx)^{t_\text{path}} \right) .
\]

The shape of the rescaled distributions, and hence the characteristic exponents \( \theta_\text{path} \) and \( t_\text{path} \), depend on the universality class. Not surprisingly, paths on ideal trees are well described by the Gaussian distribution, i.e. \( \theta_\text{path} = 0 \) and \( t_\text{path} = 2 \). Fitted values for the other cases are listed in Table SI. Given the limited range of available path lengths \( l \), we have found no meaningful
way to estimate asymptotic values. We have then simply
taken the average of the available fitted values (see bold-
faced numbers in Table SII). Again, the observed values
can be given a physical interpretation.

The exponent $\theta_{\text{path}}$ describes the reduction of the con-
tact probability, Eq. (15), relative to a naive Gaussian
estimate. Importantly, it is a genuinely novel exponent,
\textit{i.e.} it is independent from all other exponents
discussed in Refs. \cite{6,7} and in this work. In the case of self-avoiding walks, $\theta$ is related to the entropy ex-
ponent $\gamma$, Eq. (16) \cite{24,30}. Interestingly, Grosberg and
and colleagues argued \cite{3} that the identical Flory predictions
of $\nu = 3/(d + 2)$ for self-avoiding walks and for the
path statistics in melts of annealed lattice trees sug-
gests a deeper analogy between the two problems \cite{4}.
Using $\gamma_{2d} \approx 1.344$ and $\gamma_{3d} \approx 1.162$ for two and three-
dimensional self-avoiding walks \cite{30} and Eq. (16) sug-
ests $\theta_{\text{path,}2d} \approx 0.459$ and $\theta_{\text{path,}3d} \approx 0.276$. In particular,
the $3d$ value is in very good agreement with our finding
$\theta_{3d} = 0.28 \pm 0.02$ (Tables I and SII), while the $2d$ value
appears smaller than the reported $\theta_{2d} = 0.63 \pm 0.04$. No-
tice though, that these exponents were measured for path
length $l = O(50)$ and then finite-size effects may likely
induce a bias on the final result.

The exponent $t_{\text{path}}$ controls the non-linear path elas-
ticity at large elongations. The measured effective values can be compared to the Fisher-Pincus rela-
tion, Eq. (19), for self-avoiding walks \cite{33,54}

$$t_{\text{path}} = \frac{1}{1 - \nu_{\text{path}}}, \quad (35)$$

where specific values for $\nu_{\text{path}}$ are taken from Refs. \cite{6,7},
see bottom panel of Table III (columns (a) and (b)). In
general, agreement is overall good. The only exception is
for 3d self-avoiding trees with quenched ideal statistics,
which, again, may be ascribed to the limited range of
path lengths of our simulated trees. As for $t_1$ and $t_2$
and being a function of $\nu_{\text{path}}$, only, specific values for $t_{\text{path}}$ can be also obtained by using the Flory results \cite{33,54} for $\nu_{\text{path}}$
(top panel of Table III): again, for most of the cases, there
exist fair agreement with numerical predictions.

D. Conformational statistics of trees

Fig. 4 (left panels) shows distributions $p_N(\vec{r})$ of vec-
tors $\vec{r}$ connecting all tree nodes. The data superim-
pose, when expressed as functions of the scaled distances,
$x = |\vec{r}| / \sqrt{2(R_g^2(N))}$:

$$p_N(\vec{r}) = \frac{1}{(2R_g^2(N))^{3/2}} \frac{q(\sqrt{2(R_g^2(N))})}{q(|\vec{r}|)} . \quad (36)$$

Again, the distributions are in excellent agreement with
the RdC form (Eqs. (18), (20) and (21) and orange lines
in Fig. 3):

$$q(x) = C x^{t_{\text{tree}}} \exp \left(- (Kx)^{t_{\text{tree}}} \right) . \quad (37)$$

FIG. 4: Probability distribution functions, $p_N(r)$, of spatial
distances, $r$, between pairs of nodes. Orange solid lines cor-
respond to the Redner-des Cloizeaux distribution function,
Eq. (37), with parameters $\theta_{\text{tree}}$ and $t_{\text{tree}}$, obtained from the
best fits to data with $N = 1800$ (ideal and self-avoiding trees)
and $N = 900$ (2d and 3d melt of trees), see Table SIII for
detailed values of fit parameters. Insets: same plots in log-log
scale.

The extracted exponents and corresponding extrapolations
to $N \to \infty$ are listed in Table SIII.

In the following, we relate the characteristic exponents
$\theta_{\text{tree}}$ and $t_{\text{tree}}$ to our previous results by using Eqs. (34)
and (28) together with the convolution identity

$$p_N(r) = \int_0^\infty p_N(r|l) p_N(l) \, dl , \quad (38)$$

which states that the local density can be calculated by
adding up the contributions from paths of all possible
length, $1 \leq l \leq N$. The behavior of $p_N(r)$ for large
distances, $r > R_g$, can be estimated from the contour
distance $l^*(r)$, which makes the dominant contribution
to particle pairs found at the spatial distance $r$. Com-
bing the arguments of the compressed exponentials in
Eqs. (28) and (34), this requires the minimization of

$$\left( \frac{l}{(L(N))} \right)^{t_1} + \left( \frac{r}{\sqrt{(R^2(l))}} \right)^{t_{\text{path}}}$$

and yields

$$t_{\text{tree}} = \frac{t_1 t_{\text{path}}}{t_1 + t_{\text{path}} \nu_{\text{path}}} = \frac{1}{1 - \nu} . \quad (39)$$

Results from computer simulations for asymptotic ex-
ponents $t_{\text{tree}}$ and $\nu$ \cite{44} support well this relation (see
bottom panel of Table III columns (a) and (b)).
In the limit of small distances, \( r < R_g \), there are two possibilities. If there is no power law divergence in the small \( l \) limit, the integral is dominated by contributions from long paths with \( \langle R^2(l) \rangle \gg r^2 \), allowing to set the exponential term in Eq. (34) equal to one. The only \( r \)-dependence comes through the explicit \( r^{\theta_{path}} \) term and hence

\[
\theta_{tree} = \theta_{path} \quad \text{if} \quad \theta_{path} < \frac{1}{\nu} - d \quad (40)
\]

In the opposite limit, short paths dominate. The apparent divergence of the integrand in the limit \( l \to 0 \) is removed by the exponential tail of Eq. (34): paths with vanishing contour lengths up to \( l \sim r^{1/\nu_{path}} \) do not contribute to the monomer density for finite spatial distances \( r \). For longer paths, we can set the exponential to one. In this case

\[
\theta_{tree} = \frac{1}{\nu} - d \quad \text{if} \quad \frac{1}{\nu} - d < \theta_{path} \quad (41)
\]

Summarizing

\[
\theta_{tree} = \min(\theta_{path}, \frac{1}{\nu} - d) \quad (42)
\]

\[
= \begin{cases} 0 & \text{for ideal trees in } d \leq 4 \\ \frac{1}{\nu} - d & \text{else} \end{cases} \quad (43)
\]

since \( \theta_{path} \equiv 0 \) for ideal trees and since we expect \( \theta_{path} > 0 \) and \( \nu \geq 1/d \) for interacting trees. Table II compares the asymptotic results to theoretical predictions. Again, the general agreement is fairly good. Finally, as for \( \theta_l \), \( t_l \) and \( t_{path} \), specific values for \( \theta_{tree} \) and \( t_{tree} \) can be calculated by restoring to the Flory results for \( \nu \) (top panel of Table II). Once again, the predictions prove to be remarkably accurate.

To conclude the section, in Fig. S1 in Supplemental Material we focus on distribution functions of monomers around the tree center of mass. Clearly, for the central node this distribution is Gaussian. On the other hand, distant nodes can not distinguish between the central node and the tree center of mass and their positions hence follow again a RdC distribution. Averaged over node identities, the monomer distribution around the tree center of mass seems to become Gaussian for self-avoiding trees, but not for ideal trees or trees in melt. Interestingly, the latter effect was already noted a long time ago for ideal linear chains [44].

### E. Self-contacts

We turn then to the average number of self-contacts per tree, \( \langle N_c(N) \rangle \sim N^{\gamma_c} \) (l.h. panel of Fig. [5] and Table SIV). Consider an arbitrary pair of monomers. The probability to find them in close contact scales as \( N^{-\nu(d + \theta_{tree})} \). Since there are \( \mathcal{O}(N^2) \) different monomer pairs, we have

\[
\gamma_c = \frac{2 - \nu(d + \theta_{tree})}{4} \quad (44)
\]

\[
= \begin{cases} 2 - \frac{4}{d} & \text{for ideal trees in } d \leq 4 \\ 1 & \text{else} \end{cases}
\]

This prediction compares extremely well with our numerical estimates for \( \gamma_c \), see Table II. Note that the mean-field estimate \( \gamma_c = 2 - d\nu \) holds only for ideal trees in \( d \leq 4 \) dimensions. The melt case is marginal in that we expect \( \nu = 1/d \) and thus \( \gamma_c = 1 \) by using the estimated asymptotic values of \( \nu \) in 2d and 3d [7] and \( \theta_{tree} \), the different values for \( \gamma_c \) compare well for all studied ensembles (see bottom panel of Table II columns (a) and (b)). In all other cases, \( \gamma_c \) is 1 independently of \( \nu \), \( \theta_{path} \) and \( \theta_{tree} \), indicating that the local monomer density is finite and independent of tree size. This is yet another illustration of the subtle cancellation of errors in Flory arguments, which are built on the mean-field estimates of contact probabilities [20].

For tree melts, we have also considered the average number of contacts between nodes on different trees, \( \langle N_c(N) \rangle \sim N^{\beta} \) (r.h. panels of Fig. [5] and Tables SIV). In the melt, the average number of contacts per node \( \langle N_c(N) \rangle \sim \langle N_c(N) \rangle_{inter} \) is \( N \)-independent (see also Table SIV), hence \( \beta \approx 1 - \Delta \) where \( \Delta \) is the exponent of the power-law correction to the large-\( N \) behavior of \( \langle N_c(N) \rangle \): \( \langle N_c(N) \rangle \approx a N^{\gamma_c(1 - b N^{-\Delta})} = a N (1 - b N^{-\Delta}) \) with \( a \) and \( b \) numerical prefactors. \( \Delta \) can be calculated by considering the two leading terms in Eq. (33) for small \( r \)'s after substituting the upper bound of the integral with \( \mathcal{O}(N^\nu) \). Since \( \theta_{path} > \frac{1}{\nu} - d \) we get \( p_N(r) \sim (\frac{r}{N})^{1/\nu-\frac{d}{\nu}-1} \mathcal{O}(\frac{r}{N})^{d+\theta_{path}-1/\nu} \). The average number of self-contacts per tree \( \langle N_c(N) \rangle \) is proportional to the integral of the former expression from 0 to some small cut-off spatial distance, or \( \langle N_c(N) \rangle = a N (1 - b N^{1-\nu(d + \theta_{path})}) \). Consequently, \( \Delta = 1 - \nu(d + \theta_{path}) \).

\[
\beta = 1 - \Delta = 2 - \nu(d + \theta_{path}) \quad . \quad (45)
\]

In particular, Eq. (15) implies that \( \beta < 1 \). By employing the asymptotic values of \( \nu \) [7] and \( \theta_{path} \), Eq. (15) shows good agreement with direct estimates of \( \beta \) values (see bottom panel of Table II columns (a) and (b)).

### V. SUMMARY AND CONCLUSION

In the present article, we have pursued our investigation of the conformational statistics of various types of lattice trees with volume interactions [3, 5, 7]. 2d and 3d melts of lattice trees with annealed connectivity as well as 3d self-avoiding lattice trees with annealed and with quenched ideal connectivity. The well understood case of ideal, non-interacting lattice trees with annealed connectivity [20, 21] always serves as a useful reference. Here we have complemented the earlier analyses [6, 7] of
Eqs. (27,28), (33,34) and (36,37) of the type

\[
p_{N}(r) = \frac{1}{(N^{2})_{N}}^{d/2} q \left( \frac{|r|}{\sqrt{(r^{2})_{N}}} \right)
\]

\[
q(x) = C(\theta, t) |x|^{\theta} \exp \left( -K(\theta, t) |x|^{t} \right)
\]

which are fully characterised by pairs of additional exponents, \( \theta \) and \( t \), summarised in Table I. The various exponents \( t \) describe the compressed exponential large distance (large path length) behavior of the distribution. Our results suggest, that they obey generalized Fisher-Pincus \([33, 34]\) relations, Eqs. \([32, 35]\), and \([39]\). The exponents \( \theta \) characterize small distance (small path length) power law behavior and are hence related to contact probabilities (Eqs. \([40]\) and \([41]\)). We have related them to each other and the other tree exponents (Eqs. \([31, 34]\) and \([37]\)). The only exception is the exponent \( \theta_{\text{path}} \) for the small distance behavior of the path end-to-end distance distribution. The situation is similar to the well-known case of linear self-avoiding walks, where the corresponding exponent \( \theta \) and the closure probability are related to the entropy exponent \( \gamma \), which can not be predicted by Flory theory. Additional work is required to corroborate the proposed relation \([4]\) between the self-avoiding walk exponents and those characterising tree melts.

In conclusion, interacting randomly branching polymers exhibit an extremely rich behaviour and swell by a combination of modified branching and path stretching \([3]\). As previously shown \([2]\), the average behaviour \([8, 9]\) in the various regimes and crossovers can be well described by a generalised Flory theory. Our present results demonstrate, that this is not the case for distribution functions. Nonetheless, their non-Gaussian functional form can be characterised by a small set of exponents, which are related to each other and the standard trees exponents. The good agreement of the predicted relations with the numerical data suggests that we now dispose of a coherent framework for describing the connectivity and conformational statistics of interacting trees in a wide range of situations.

TABLE I: Critical exponents for distribution functions of lattice trees. (Top panel) Theoretical predictions by using the results of the Flory theory for $\nu_{path}$, $\rho$ and $\nu$ [4,5]. (Bottom) Corresponding numerical results obtained by: (a) Extrapolation to $N \to \infty$ of “effective” exponents for trees of size $N$, see also Supplemental Tables SI-IV for details. (b) Substitution of numerical asymptotic exponents (from Refs. [4,5] and this work) into the scaling relations summarized in the top. Mean values and corresponding error bars have been rounded to the first significant decimal digit.

I. Supplemental Figures 13

II. Supplemental Tables 15
I. SUPPLEMENTAL FIGURES
Fig. S 1: Distribution functions of spatial distances, $\delta r$, of nodes from the tree center of mass, compared to the Gaussian distribution (yellow line). For ideal trees, $p_N(\delta r)$ is not Gaussian, an effect similar to what reported a long time ago for ideal linear chains [44]. Interestingly, for self-avoiding trees $p_N(\delta r)$ becomes almost Gaussian. Conversely, some noticeable deviations appear in melts of trees, especially in the 2d case. In fact, given the node $i$ at spatial position from the center of mass $\delta_{c,r}$ and from the tree center $\delta_r$, one might be tempted to rationalise this behaviour by applying the convolution relation $p_N(\delta r_i) = \int_0^{\infty} d\delta r_c p_N(\delta r_c) p_N(\delta_{c,r_i})$. However, this would be incorrect as $\delta r_c$ and $\delta_{c,r_i}$ are not statistically independent. Insets show the same plots in log-log scale.

- \( \tilde{Q} \): 2.23 ± 0.01

Table S I: Path length statistics. Effective exponents \( \theta_l \) and \( t_l \) obtained by best fits of the Redner-des Cloizeaux function, Eq. (28) main paper, to the numerical distributions \( p_d(l) \) of linear paths of length \( l \) at different \( N \) (Fig. 2, main paper). Extrapolations to \( N \rightarrow \infty \) were obtained by employing three- (\( \Delta \) as free parameter) and two-parameter (\( \Delta \) fixed to 1) fit functions, see Sec. IIIC main paper. Final estimates with corresponding statistical and systematic errors are given at the end of the table (in boldface).
Table S II: Conformational statistics of linear paths. Effective exponents $\theta_{\text{path}}$ and $t_{\text{path}}$ obtained by best fits of the Redner-des Cloizeaux function, Eq. (34) main paper, to the numerical distributions $p_N(r|l)$ of end-to-end spatial distances of linear paths of length $l$ at given $N$ (Fig. 3, main paper). Final estimates with statistical and systematic errors are given at the end of the table (in boldface).

### Table S III: Conformational statistics of trees.

Effective exponents $\theta_{\text{tree}}$ and $t_{\text{tree}}$ obtained by best fits the Redner-des Cloizeaux distribution function, Eq. (37) main paper, to the numerical distributions $p_N(r)$ of spatial distances $r$ between tree nodes at different $N$ (Fig. 4, main paper). Extrapolations to $N \to \infty$ were obtained by employing three- ($\Delta$ as free parameter) and two-parameter ($\Delta$ fixed to 1) fit functions, see Sec. III C main paper. The three-parameter fit fails for $\theta_{\text{tree}}$ of self-avoiding trees with quenched ideal connectivity. In this case, the reported statistical and systematic errors were based on the ones of ideal trees where: (statistical error for three-parameter fit) $\approx 20$ (statistical error for two-parameter fit) $\approx 2$ (systematic error). Final estimates with corresponding statistical and systematic errors are given at the end of the table (in boldface).
### Table S IV:

| | Ideal trees | 2d melt of trees | 3d melt of trees | Self-avoid. trees, annealed connect. | Self-avoid. trees, quen. ideal connect. |

For ideal trees and melt of trees, the numerical extrapolation scheme follows Ref. [10] and was the same adopted in our former works [6, 7]. It combines best fits to the data of: (1) single power-law behavior $(\Delta = 0): \log \langle N_e \rangle = c_1 + \gamma_c^{\Delta=0} \log N$, for data corresponding to the 3 largest $N$ of each set) and (2) power-law behavior with a correction-to-scaling term $(\Delta \neq 0): \log \langle N_e \rangle = c_2 + c_3 N^{\Delta-\Delta_c} + \gamma_c^{\Delta \neq 0} \log N$, for data with $N \geq 10$. The reported values (last line of the table) are calculated as: $\gamma_c = \gamma_c^{\Delta=0} + \gamma_c^{\Delta \neq 0}$ (spread between $\gamma_c^{\Delta=0}$ and $\gamma_c^{\Delta \neq 0}$), the last being an estimate for systematic errors due to finite-size effects [10]. Equivalent expressions hold for $\langle N_e^{\text{inter}} \rangle$. For self-avoiding trees, finite-size effects appear completely negligible: then, $\gamma_c$ was obtained by fitting data for $N \geq 450$ to just the single power-law function.
