ABSTRACT

Understanding cosmic reionization requires the identification and characterization of early sources of hydrogen-ionizing photons. The 2012 Hubble Ultra Deep Field (UDF12) campaign has acquired the deepest infrared images with the Wide Field Camera 3 aboard Hubble Space Telescope and, for the first time, systematically explored the galaxy population deep into the era when cosmic microwave background (CMB) data indicate reionization was underway. The UDF12 campaign thus provides the best constraints to date on the abundance, luminosity distribution, and spectral properties of early star-forming galaxies. We synthesize the new UDF12 results with the most recent constraints from CMB observations to infer redshift-dependent ultraviolet (UV) luminosity densities, reionization histories, and electron scattering optical depth evolution consistent with the available data. Under reasonable assumptions about the escape fraction of hydrogen-ionizing photons and the intergalactic medium clumping factor, we find that to fully reionize the universe by redshift \( z \sim 6 \) the population of star-forming galaxies at redshifts \( z \sim 7–9 \) likely must extend in luminosity below the UDF12 limits to absolute UV magnitudes of \( M_{\text{UV}} \sim -13 \) or fainter. Moreover, low levels of star formation extending to redshifts \( z \sim 15–25 \), as suggested by the normal UV colors of \( z \sim 7–8 \) galaxies and the smooth decline in abundance with redshift observed by UDF12 to \( z \sim 10 \), are additionally likely required to reproduce the optical depth to electron scattering inferred from CMB observations.

Key words: dark ages, reionization, first stars – galaxies: evolution – galaxies: formation

1. INTRODUCTION

The process of cosmic reionization remains one of the most important outstanding problems in galaxy formation and cosmology. After recombination at \( z \approx 1090 \) (Hinshaw et al. 2012), gas in the universe was mostly neutral. However, observations of the Gunn & Peterson (1965) trough in quasar spectra (e.g., Fan et al. 2001, 2002, 2003, 2006b; Djorgovski et al. 2001) indicate that intergalactic gas has become almost fully reionized by redshift \( z \sim 5 \). The electron scattering optical depth inferred from cosmic microwave background (CMB) observations suggests that if the universe was instantaneously reionized, then reionization would occur as early as redshift \( z \sim 10 \) (Spergel et al. 2003; Hinshaw et al. 2012). Given the dramatic decline in the abundance of quasars beyond redshift \( z \sim 6 \), they very likely cannot be a significant contributor to cosmic reionization (e.g., Willott et al. 2010; Fontanot et al. 2012) even though quasars have been discovered as early as \( z \sim 7 \) (Mortlock et al. 2011). Star-forming galaxies at redshifts \( z \gtrsim 6 \) have therefore long been postulated as the likely agents of cosmic reionization, and their time-dependent abundance and spectral properties are thus crucial ingredients for understanding how intergalactic hydrogen became reionized (for reviews, see Fan et al. 2006a; Robertson et al. 2010; Loeb & Furlanetto 2012).

We present an analysis of the implications of the 2012 Hubble Ultra Deep Field\(^8\) (UDF12) campaign results on the abundance and spectral characteristics of galaxies at \( z \sim 7–12 \) for the reionization process. The UDF12 campaign is a 128-orbit Hubble Space Telescope (HST) program (GO 12498, PI: Ellis) with the infrared (IR) channel on the Wide Field Camera 3 (WFC3/IR) that acquired the deepest ever images in the IR with HST in the Hubble Ultra Deep Field (HUDF) in Fall 2012 (the UDF12 project and data overview are described in Ellis et al. 2013 and Koekemoer et al. 2013). Combined with previous HUDF observations (GO 11563, PI: G. Illingworth; GO 12060, 12061, 12062, PIs: S. Faber and H. Ferguson; GO 12099, PI: A. Riess), the UDF12 imaging reaches depths of \( Y_{105} = 30 \), \( J_{125} = 29.5 \), \( J_{140} = 29.5 \), and \( H_{160} = 29.5 \) (5σ AB magnitudes). The UDF12 observations have provided the first determinations of the galaxy abundance at redshifts \( 8.5 \leq z \leq 12 \) (Ellis et al. 2013), precise determinations of the galaxy luminosity function at redshifts \( z \sim 7–8 \) (Schenker et al. 2012a; McLure et al. 2012), robust ultraviolet (UV) spectral slope measurements at \( z \sim 7–8 \) (Dunlop et al. 2012b), and size–luminosity relation measures at redshifts \( z \sim 6–8 \) (Ono et al. 2012a).

Our earlier UDF12 publications already provide some new constraints on the role that galaxies play in cosmic reionization and the duration of the process. In Ellis et al. (2013), we argued that continuity in the declining abundance of star-forming galaxies over \( 6 < z < 10 \) (and possibly to \( z \sim 12 \)) implied the likelihood of further star formation beyond the redshift limits currently probed. Likewise, in Dunlop et al. (2012b)...
(2012b), the constancy of the UV continuum slope measured in $z \approx 7$–9 galaxies over a wide range in luminosity supports the contention that the bulk of the stars at this epoch are already enriched by earlier generations. Collectively, these two results support an extended reionization process.

We synthesize these UDF12 findings with the recent nine-year Wilkinson Microwave Anisotropy Probe (WMAP) results (Hinshaw et al. 2012) and stellar mass density measurements (Stark et al. 2013) to provide new constraints on the role of high-redshift star-forming galaxies in the reionization process. Enabled by the new observational findings, we perform Bayesian inference using a simple parameterized model for the evolving UV luminosity density to find reionization histories, stellar mass density evolutions, and electron scatter optical depth evolutions consistent with the available data. We limit the purview of this paper to empirical modeling of the reionization process, and comparisons with more detailed galaxy formation models will be presented in a companion paper (P. Dayal et al., in preparation).

Throughout this paper, we assume the nine-year WMAP cosmological parameters (as additionally constrained by external CMB data sets; $h = 0.705$, $\Omega_m = 0.272$, $\Omega_L = 0.728$, $\Omega_b = 0.04885$). Magnitudes are reported using the AB system (Oke & Gunn 1983). All Bayesian inference and maximum likelihood fitting is performed using the MultiNest code (Feroz & Hobson 2008; Feroz et al. 2009).

2. THE PROCESS OF COSMIC REIONIZATION

Theoretical models of the reionization process have a long history. Early analytic and numerical models of the reionization process (e.g., Madau et al. 1999; Miralda-Escudé et al. 2000; Gnedin 2000; Barkana & Loeb 2001; Razoumov et al. 2002; Wyithe & Loeb 2003; Ciardi et al. 2003) highlighted the essential physics that give rise to the ionized intergalactic medium (IGM) at late times. In the following description of the cosmic reionization process, we follow most closely the modeling of Madau et al. (1999), Bolton & Haehnelt (2007b), Robertson et al. (2010), and Kuhlen & Faucher-Giguère (2012), but there has been closely related recent work by Ciardi et al. (2012) and Jensen et al. (2013).

The reionization process is a balance between the recombination of free electrons with protons to form neutral hydrogen and the ionization of hydrogen atoms by cosmic Lyman continuum photons with energies $E > 13.6$ eV. The dimensionless volume filling fraction of ionized hydrogen $Q_{\text{HI}}$ can be expressed as a time-dependent differential equation capturing these competing effects as

$$\dot{Q}_{\text{HI}} = \frac{n_{\text{ion}}}{n_{\text{HI}}} - \frac{Q_{\text{HI}}}{t_{\text{rec}}},$$

where the dotted quantities are time derivatives.

The comoving density of hydrogen atoms

$$\langle n_{\text{HI}} \rangle = X_p \Omega_b \rho_c$$

depends on the primordial mass-fraction of hydrogen $X_p = 0.75$ (e.g., Hou et al. 2011), the critical density $\rho_c = 1.8787 \times 10^{-29} h^{-2} \text{ g cm}^{-2}$, and the fractional baryon density $\Omega_b$.

As a function of redshift, the average recombination time in the IGM is

$$t_{\text{rec}} = [C_{\text{HI}} \alpha_B(T)(1 + Y_p/4X_p)(n_{\text{HI}})(1 + z)^3]^{-1},$$

where $\alpha_B(T)$ is the case B recombination coefficient for hydrogen (we assume an IGM temperature of $T = 20,000$ K), $Y_p = 1 - X_p$ is the primordial helium abundance (and accounts for the number of free electrons per proton in the fully ionized IGM, e.g., Kuhlen & Faucher-Giguère 2012), and $C_{\text{HI}} \equiv (n_{\text{HI}}^2)/(n_{\text{HI}})^2$ is the “clumping factor” that accounts for the effects of IGM inhomogeneity through the quadratic dependence of the recombination rate on density.

Simulations suggest that the clumping factor of IGM gas is $C_{\text{HI}} \approx 1$–6 at the redshifts of interest (e.g., Sokasian et al. 2003; Iliev et al. 2006; Pawlik et al. 2009; Shull et al. 2012; Finlator et al. 2012). While early hydrodynamical simulation studies suggested that the clumping factor could be as high as $C_{\text{HI}} \sim 10$–40 at redshifts $z \lesssim 8$ (e.g., Gnedin & Ostriker 1997), recent studies that separately identify IGM and interstellar medium (ISM) gas in the simulations and employ a more detailed modeling of the evolving UV background have found lower values of $C_{\text{HI}}$. An interesting study of the redshift evolution of the clumping factor was provided by Pawlik et al. (2009, see their Figures 5 and 7). At early times in their simulations ($z \gtrsim 10$), the clumping factor was low ($C_{\text{HI}} < 3$) but increased with decreasing redshift at a rate similar to predictions from the Miralda-Escudé et al. (2000) model of the evolving IGM density probability distribution function. In the absence of photoheating, at lower redshifts ($z \lesssim 9$) the clumping factor would begin to increase more rapidly than the Miralda-Escudé et al. (2000) prediction to reach $C_{\text{HI}} \sim 10$–20 by $z \sim 6$. In the presence of photoheating, the evolution of the clumping factor depends on the epoch when the uniform UV background becomes established. If the IGM was reheated early ($z \sim 10$–20), then the predicted rise in clumping factor breaks after the UV background is established and increases only slowly to $C_{\text{HI}} \sim 3$–6 at late times ($z \sim 6$). If instead, and perhaps more likely, the IGM is reheated later (e.g., $z \sim 6$–8), then the clumping factor may actually decrease at late times from $C_{\text{HI}} \sim 6$–10 at $z \sim 8$ to $C_{\text{HI}} \sim 3$–6 at $z \sim 6$.

The results of these simulations (e.g., Pawlik et al. 2009; Finlator et al. 2012) in part motivate our choice to treat the clumping factor as a constant $C_{\text{HI}} \sim 3$ since over a wide range of possible redshifts for the establishment of the UV background the clumping factor is expected to be $C_{\text{HI}} \sim 2$–4 at $z \lesssim 12$ (see Figure 5 of Pawlik et al. 2009) and lower at earlier times. In comparison with our previous work (Robertson et al. 2010), where we considered $C_{\text{HI}} = 2$–6 and frequently used $C_{\text{HI}} = 2$ in Equation (3), we will see that our models complete reionization somewhat later when a somewhat larger value of $C_{\text{HI}}$ is more appropriate. However, we note that the end of the reionization process may be more complicated than what we have described above (see, e.g., Section 9.2.1 of Loeb & Furlanetto 2012). As reionization progresses, the ionized phase penetrates more and more deeply into dense clumps within the IGM—the material that will later form the Ly$\alpha$ forest (and higher column density systems). These high-density clumps recombine much faster than average, so $C_{\text{HI}}$ may increase throughout reionization (Furlanetto & Oh 2005). Combined with the failure of Equation (1) to model the detailed distribution of gas densities in the IGM, we expect our admittedly crude approach to fail at the tail end of reionization. Fortunately, we are primarily concerned with the middle phases of reionization here, so any unphysical behavior when $Q_{\text{HI}}$ is large is not important for us.

The comoving production rate $\dot{n}_{\text{ion}}$ of hydrogen-ionizing photons available to reionize the IGM depends on the intrinsic productivity of Lyman continuum radiation by stellar populations within galaxies parameterized in terms of the rate of...
hydrogen-ionizing photons per unit UV (1500 Å) luminosity $\xi_{\text{ion}}$ (with units of erg$^{-1}$ Hz), the fraction $f_{\text{esc}}$ of such photons that escape to affect the IGM, and the total UV luminosity density $\rho_{\text{UV}}$ (with units of erg s$^{-1}$ Hz$^{-1}$ Mpc$^{-3}$) supplied by star-forming galaxies to some limiting absolute UV magnitude $M_{\text{UV}}$. The product

$$\dot{n}_{\text{ion}} = f_{\text{esc}} \xi_{\text{ion}} \rho_{\text{UV}}$$

then determines the newly available number density of Lyman continuum photons per second capable of reionizing intergalactic hydrogen. We note that the expression of $\dot{n}_{\text{ion}}$ in terms of UV luminosity density rather than star formation rate (cf. Robertson et al. 2010) is largely a matter of choice; stellar population synthesis models with assumed star formation histories are required to estimate $\xi_{\text{ion}}$ and using the star formation rate density $\dot{\phi}_{\odot}$ in Equation (4) therefore requires no additional assumptions. Throughout this paper, we choose $f_{\text{esc}} = 0.2$. As shown by Ouchi et al. (2009), escape fractions comparable to or larger than $f_{\text{esc}} = 0.2$ during the reionization epoch are required for galaxies with typical stellar populations to contribute significantly. We also consider an evolving $f_{\text{esc}}$ with redshift, with the results discussed in Section 6.2 below.

The advances presented in this paper come primarily from the new UDF12 constraints on the abundance of star-forming galaxies over $6.5 < z < 12$, the luminosity functions down to $M_{\text{UV}} \simeq -17$, and robust determinations of their UV continuum colors. For the latter, in Section 3, we use the UV spectral slope of high-redshift galaxies by Dunlop et al. (2012b) and the stellar population synthesis models of Bruzual & Charlot (2003) to inform a choice for the number $\xi_{\text{ion}}$ of ionizing photons produced per unit luminosity. For the former, the abundance and luminosity distribution of high-redshift galaxies determined by Ellis et al. (2013), Schenker et al. (2012a), and McLure et al. (2012) provide estimates of the evolving UV luminosity density $\rho_{\text{UV}}$. The evolving UV luminosity density supplied by star-forming galaxies brighter than some limiting magnitude $M_{\text{UV}}$ is simply related to an integral of the luminosity function as

$$\rho_{\text{UV}}(z) = \int_{-\infty}^{M_{\text{UV}}} \Phi(M) L(M) dM,$$

where $L$ is the luminosity and the functional form of the galaxy luminosity function is often assumed to be a Schechter (1976) function

$$\Phi(M) = 0.4 \ln 10 \phi_* [10^{0.4(M_* - M)}]^{1+\alpha} \exp[-10^{0.4(M_* - M)}]$$

parameterized in terms of the normalization $\phi_*$ (in units of Mpc$^{-3}$ mag$^{-1}$), the characteristic galaxy magnitude $M_*$, and the faint-end slope $\alpha$. Each of these parameters may evolve with redshift $z$, which can affect the relative importance of faint galaxies for reionization (e.g., Oesch et al. 2009; Bouwens et al. 2012b). In Sections 4 and 4.1 below, we present our method of using the previous and UDF12 data sets to infer constraints on the luminosity density as a function of redshift and limiting magnitude.

### 2.1. Stellar Mass Density as a Constraint on Reionization

The UV luminosity density is supplied by short-lived, massive stars and therefore reflects the time rate of change of the stellar mass density $\rho_*(z)$. In the context of our model, there are two routes for estimating the stellar mass density. First, we can integrate the stellar mass density supplied by the star formation rate inferred from the evolving UV luminosity density as

$$\rho_*(z) = (1 - R) \int_{\infty}^{z} \eta_{\text{sd}'}(z') \rho_{\text{UV}}(z') \frac{dt}{dz'},$$

where $\eta_{\text{sd}'}(z)$ provides the stellar population model-dependent conversion between UV luminosity and star formation rate (in units $M_\odot$ yr$^{-1}$ erg$^{-1}$ s Hz), $R$ is the fraction of mass returned from a stellar population to the ISM (28% for a Salpeter 1955 model after ~10 Gyr for a 0.1–100 $M_\odot$ IMF), and $dt/dz$ gives the rate of change of universal time per unit redshift (in units of yr). While $\eta_{\text{sd}'}(z)$ is in principle time-dependent, there is no firm evidence yet of its evolution and we adopt a constant value throughout.

While the evolving stellar mass density can be calculated in our model, the observational constraints on $\rho_*$ have involved integrating a composite stellar mass function constructed from the UV luminosity function and a stellar mass to UV luminosity relation (Gonzalez et al. 2011; Stark et al. 2013, see also Labbe et al. 2012). Using near-IR observations with the Spitzer Space Telescope, stellar masses of UV-selected galaxies are measured as a function of luminosity. Stark et al. (2013) find that the stellar mass–L$_{\text{UV}}$ relation, corrected for nebular emission contamination, is well described by

$$\log m_* = 1.433 \log L_{\text{UV}} - 31.99 + f_\gamma(z),$$

where $m_*$ is the stellar mass in $M_\odot$, $L_{\text{UV}}$ is the UV luminosity in erg s$^{-1}$ Hz$^{-1}$, and $f_\gamma(z) = [0, -0.03, -0.18, -0.40]$ for redshift $z \approx [4, 5, 6, 7]$. The stellar mass density will then involve an integral over the product of the UV luminosity function and the stellar mass $m_*(L_{\text{UV}})$. However, the significant scatter in the $m_*(L_{\text{UV}})$ relation ($\sigma \approx 0.5$ in $\log m_*$; see Gonzalez et al. 2011; Stark et al. 2013) must be taken into account. The Gaussian scatter $p[M' - M(\log m_*)]$ in luminosity contributing at a given $\log m_*$ can be incorporated into the stellar mass function $dn_*/d\log m_*$ with a convolution over the UV luminosity function. We write the stellar mass function as

$$\frac{dn_*/d\log m_*}{d\log m_*} = \frac{dM}{d\log m_*} \int_{-\infty}^{M_{\text{UV}}} \Phi(M') p[M' - M(\log m_*)] dM'.$$

For vanishing scatter, Equation (9) would give simply $dn_*/d\log m_* = \Phi[M(m_*)] \times dM/dm_*$. The stellar mass density $\rho_*$ can be computed by integrating this mass function as

$$\rho_*(<m_*,z) = \int_{-\infty}^{\log m_*} \frac{dn_*/d\log m_*}{d\log m_*} m'_* d\log m'_*.$$

A primary feature of the stellar mass function is that the stellar mass–UV luminosity relation and scatter flattens it relative to the UV luminosity function. Correspondingly, the stellar mass density converges faster with decreasing stellar mass or luminosity than does the UV luminosity density (Equation (5)). The stellar mass density then serves as an additional, integral constraint on $\dot{n}_{\text{ion}}$.

### 2.2. Electron Scattering Optical Depth

Once the evolving production rate of ionizing photons $\dot{n}_{\text{ion}}$ is determined, the reionization history $Q_{\text{HII}}(z)$ of the universe can be calculated by integrating Equation (1). An important integral constraint on the reionization history is the electron scattering
optical depth $\tau$ inferred from observations of the CMB. The optical depth can be calculated from the reionization history as a function of redshift $z$ as

$$
\tau(z) = \int_0^z c(m_1) \sigma T f_e Q_{HI}(z') H(z')(1+z')^2 dz',
$$

where $c$ is the speed of light, $\sigma T$ is the Thomson cross section, and $H(z)$ is the redshift-dependent Hubble parameter. The number $f_e$ of free electrons per hydrogen nucleus in the ionized IGM depends on the ionization state of helium. Following Kuhlen & Faucher-Giguère (2012) and other earlier works, we assume that helium is doubly ionized ($f_e = 1 + Y_e/2X_p$) at $z \leq 4$ and singly ionized ($f_e = 1 + Y_e/4X_p$) at higher redshifts. To utilize the observational constraints on $\tau$ as a constraint on the reionization history, we employ the posterior probability distribution $p(\tau)$ determined from the Monte Carlo Markov Chains (MCMC) used in the nine-year WMAP results as a marginalized likelihood for our derived $\tau$ values. This method is described in more detail in Section 5.

3. UV SPECTRAL SLOPES AND THE IONIZING PHOTON BUDGET

A critical ingredient for determining the comoving production rate of hydrogen-ionizing photons is the ratio $\xi_{\text{ion}}$ of the Lyman continuum photon emission rate per unit UV (1500 Å) luminosity spectral density of individual sources. Since Lyman continuum photons are predominately produced by hot, massive, UV-bright stars, it is sensible to expect that $\xi_{\text{ion}}$ will be connected with the UV spectral slope of a stellar population. Here, we use observational constraints on the UV slope of high-redshift galaxies determined from the UDF12 campaign by Dunlop et al. (2012b) and stellar population synthesis models by Bruzual & Charlot (2003, BC03) to estimate a physically motivated $\xi_{\text{ion}}$ consistent with the data. In this paper, we concentrate on placing constraints on $\xi_{\text{ion}}$, for a much more detailed analysis and interpretation of the UV slope results from UDF12, please see Dunlop et al. (2012b).

Prior to the UDF12 program, observations of high-redshift galaxies in the HUDF09 WFC3/IR campaign provided a first estimate of the UV spectral slopes ($\beta$, where $f_{\beta} \propto \lambda^\beta$) of $z \geq 7$ galaxies. Early results from the HUDF09 team indicated that these high-redshift galaxies had extraordinarily blue UV slopes of $\beta \approx -3$ (Bouwens et al. 2010), much bluer than well-studied starburst galaxies at lower redshifts (e.g., Meurer et al. 1999). In the intervening period before the UDF12 data were acquired, several workers argued against such extreme values (Finkelstein et al. 2010, 2012; McLure et al. 2011; Dunlop et al. 2012a; Bouwens et al. 2012a; Rogers et al. 2012). The UDF12 campaign provided significantly deeper $H_{160}$ imaging data used in the spectral slope determination (e.g., $\beta = 4.43(J_{125} - H_{160}) - 2$) at redshifts $z \sim 7$–8) and added $J_{140}$ imaging that reduces potential observational biases and enables a first UV slope determination at $z \sim 9$. These measurements were presented by Dunlop et al. (2012b), whose results are discussed in the context of the present paper in Figure 1 (data points, left panel). Dunlop et al. (2012b) measured the spectral slope $\beta$ as a function of galaxy luminosity and redshift in the range $-19.5 < M_{\text{UV}} < -17.5$ at $z \sim 7$–8. Using their reported measurements (see their Table 1), we performed simple fits of a constant to their $\beta$ values at each redshift separately and found maximum likelihood values of $\beta(z \sim 7) = -1.915$ and $\beta(z \sim 8) = -1.970$ (Figure 1, red lines in left panel) consistent with the single $M_{\text{UV}} = -18$ $z \sim 9$ measurement of $\beta(z \sim 9) = -1.80 \pm 0.63$. The 68% credibility intervals on a constant $\beta$ at each redshift (Figure 1, gray areas in left panel) suggest that across redshifts $z \sim 7$–9 galaxies are consistent with a non-evolving UV spectral slope in the range $-2.1 \leq \beta \leq -1.7$. The apparent constancy of $\beta$ with redshift avoids the need for strong assumptions about the redshift evolution of galaxy properties.

To connect these UV spectral slope determinations to a value of $\xi_{\text{ion}}$, we must rely on stellar population synthesis models. We use the standard BC03 models to extract model spectral of stellar populations with a range of star formation histories (bursts and constant star formation rates), metallicities ($Z = 0.0001$–0.05), dust absorption ($A_V \approx 0.1$–1; calculated using the Charlot & Fall 2000 dust model), and initial mass functions (IMF; Chabrier 2003 and Salpeter 1955). These models provide both the Lyman continuum produced by hot stars and the full spectral energy distributions (SEDs) of the composite stellar population per unit star formation rate (SFR) or stellar mass. We determine $\xi_{\text{ion}}$ for each model by dividing the Lyman continuum photon production rate per unit SFR or stellar mass by a 1500 Å luminosity spectral density (in erg s$^{-1}$ Hz$^{-1}$) per unit SFR or stellar mass measured with a synthetic filter with a flat response and 100 Å width. The model SFR or stellar mass then scales out of the ratio $\xi_{\text{ion}}$ (with units erg$^{-1}$ Hz$^{-1}$). By measuring the UV slope values of each model using synthetic photometry with the $J_{125}$ and $H_{160}$ total throughput response on SEDs redshifted appropriately for $z \sim 7$ observations, the value of $\xi_{\text{ion}}$ for each model $\beta$ can be studied as a function of age, metallicity, IMF, and star formation history. We have checked that our methods for measuring $\beta$ and IR colors from the synthetic model spectra reproduce results from the literature (see Robertson et al. 2007 and Figure 2 of Rogers et al. 2012).

The right panel of Figure 1 shows the $\xi_{\text{ion}}$ of a variety of BC03 constant SFR models as a function of UV slope $\beta$, over the range $-2.1 \leq \beta \leq -1.7$ suggested by the Dunlop et al. (2012b) color measurements and further constrained such that the age of the stellar populations is less than the age of the universe at redshift $z \sim 7$ ($t \approx 7.8 \times 10^8$ yr). We will limit our further discussion of BC03 models to constant SFR histories, as we find single bursts populations display too wide a range of $\xi_{\text{ion}}$ with $\beta$ to be tightly constrained by $\beta$ alone (although limits on the luminosity will constrain the available $\xi_{\text{ion}}$ for a given $\beta$ for single burst models, without the individual SED fits to objects we cannot usefully constrain such models over the wide range of luminosity and redshifts we examine).

Three broad types of BC03 constant SFR models are consistent with values of $\beta = -2$. Generically, the BC03 constant SFR models evolve from large values of $\xi_{\text{ion}}$ and large negative values of $\beta$ at early times to a roughly horizontal evolution with constant $\xi_{\text{ion}}$ with $\beta$ increasing at late times ($t \gtrsim 10^8$ yr). Metal-poor ($Z < Z_\odot$) constant SFR populations without dust produce values of $\beta$ significantly bluer (more negative) than observed at $z \sim 7$–9 (Dunlop et al. 2012b). Mature ($\gtrsim 10^9$ yr old), metal-rich ($Z \approx Z_\odot$), dust-free stellar populations evolve to a constant value of $\log \xi_{\text{ion}} \approx 24.95$–25.25 log erg$^{-1}$ Hz over the observed $\beta$ values (as Figure 1 indicates, the results are largely independent of IMF for constant SFR models). Applying a dust absorption of $A_V \sim 0.1$ using the model of Charlot & Fall (2000, with parameters $r_V = 0.25$ and an ISM attenuation fraction of 0.3) shifts the SED evolution tracks down in $\xi_{\text{ion}}$ (from dust

http://lambda.gsfc.nasa.gov
The data are broadly consistent with a connection between observations to measure the UV spectral slope $\beta$ of $z \sim 7$–9 galaxies as a function of luminosity (data points, left panel). As the data are consistent with a constant $\beta$ independent of luminosity, we have fit constant values of $\beta$ at redshifts $z \sim 7$–8 (maximum likelihood values of $\beta(z \sim 7) = -1.915$ and $\beta(z \sim 8) = -1.970$ shown as red lines, inner 68% credibility intervals shown as gray shaded regions; at $z \sim 9$ the line and shaded region reflect the best-fit value of $\beta(z \sim 9) = -1.80 \pm 0.63$). The data are broadly consistent with $\beta = -2$ (indicated with the gray band in right panel), independent of redshift and luminosity. To translate the UV spectral slope to a ratio $\xi_{\text{ion}}$ of ionizing photon production rate to UV luminosity, we use the BC03 stellar population synthesis models (right panel) assuming a constant star formation rate (SFR). The constant SFR models evolve from a declining $\xi_{\text{ion}}$ with increasing $\beta$ at early times to a relatively flat $\xi_{\text{ion}}$ at late times (we plot the values of $\xi_{\text{ion}}$ vs. $\beta$ for population ages less than the age of the universe at $z \sim 7$, $t \approx 7 \times 10^8$ yr). Three broad types of BC03 constant SFR models are consistent with values of $\beta = -2$: mature ($\geq 10^8$ yr old), metal-rich, dust-free stellar populations; mature, metal-rich stellar populations with dust ($A_v \approx 0.1$ calculated using the Charlot & Fall 2000 model); and young, metal-rich stellar populations with dust. Dust-free models are plotted with solid lines, while dusty models are shown as dashed lines. We assume the Chabrier (2003) initial mass function (IMF), but the Salpeter (1955) IMF produces similar values of $\xi_{\text{ion}}$ (dotted lines, dust-free case shown). Based on these models we optimistically assume $\log \xi_{\text{ion}} = 25.2 \log \text{erg}^{-1}$ Hz, but this value is conservative compared with assumptions widely used in the literature.

(A color version of this figure is available in the online journal.)

Figure 1. Spectral properties of high-redshift galaxies and the corresponding properties of stellar populations. Dunlop et al. (2012b) used the new UDF12 HST observations to measure the UV spectral slope $\beta$ of $z \sim 7$–9 galaxies as a function of luminosity (data points, left panel). As the data are consistent with a constant $\beta$ independent of luminosity, we have fit constant values of $\beta$ at redshifts $z \sim 7$–8 (maximum likelihood values of $\beta(z \sim 7) = -1.915$ and $\beta(z \sim 8) = -1.970$ shown as red lines, inner 68% credibility intervals shown as gray shaded regions; at $z \sim 9$ the line and shaded region reflect the best-fit value of $\beta(z \sim 9) = -1.80 \pm 0.63$). The data are broadly consistent with $\beta = -2$ (indicated with the gray band in right panel), independent of redshift and luminosity. To translate the UV spectral slope to a ratio $\xi_{\text{ion}}$ of ionizing photon production rate to UV luminosity, we use the BC03 stellar population synthesis models (right panel) assuming a constant star formation rate (SFR). The constant SFR models evolve from a declining $\xi_{\text{ion}}$ with increasing $\beta$ at early times to a relatively flat $\xi_{\text{ion}}$ at late times (we plot the values of $\xi_{\text{ion}}$ vs. $\beta$ for population ages less than the age of the universe at $z \sim 7$, $t \approx 7 \times 10^8$ yr). Three broad types of BC03 constant SFR models are consistent with values of $\beta = -2$: mature ($\geq 10^8$ yr old), metal-rich, dust-free stellar populations; mature, metal-rich stellar populations with dust ($A_v \approx 0.1$ calculated using the Charlot & Fall 2000 model); and young, metal-rich stellar populations with dust. Dust-free models are plotted with solid lines, while dusty models are shown as dashed lines. We assume the Chabrier (2003) initial mass function (IMF), but the Salpeter (1955) IMF produces similar values of $\xi_{\text{ion}}$ (dotted lines, dust-free case shown). Based on these models we optimistically assume $\log \xi_{\text{ion}} = 25.2 \log \text{erg}^{-1}$ Hz, but this value is conservative compared with assumptions widely used in the literature.

(A color version of this figure is available in the online journal.)

absorption) and to redder $\beta$, such that young, metal-rich stellar populations with dust can also reproduce values of $\beta \approx -2$ while maintaining $\log \xi_{\text{ion}} = 24.75$–25.35 log erg$^{-1}$ Hz. Moderately metal-poor models ($Z \sim 0.2$–0.4$Z_{\odot}$) with as much as $A_v \approx 0.1$ can also reproduce $\beta \approx -2$ for population ages $t > 10^8$ yr, but the most metal-poor models in this range require $t > 4 \times 10^8$ yr (an initial formation redshift of $z \gtrsim 12$ if observed at $z \approx 7$). We note that our conclusions about the connection between $\beta$ (or $J_{125} - H_{160}$ color) and the properties of stellar populations are wholly consistent with previous results in the literature (e.g., Figure 7 of Finkelstein et al. 2010).

While the $\beta$ measurements of Dunlop et al. (2012b) have greatly reduced the available BC03 stellar population model parameter space, there is still a broad allowable range of $\log \xi_{\text{ion}} \approx 24.75$–25.35 log erg$^{-1}$ Hz available for constant SFR models with UV spectral slopes of $\beta \approx -2$. We therefore adopt the value

$$\log \xi_{\text{ion}} = 25.2 \log \text{erg}^{-1} \text{Hz} \quad (12)$$

throughout the rest of the paper. This $\xi_{\text{ion}}$ is in the upper range of the available values shown in Figure 1, but is comparable to values adopted elsewhere in the literature (e.g., Kuhlen & Faucher-Giguère 2012, who assume $\log \xi_{\text{ion}} \approx 25.3$ for $\beta = -2$, see their Equations (5) and (6)).

We also considered stellar populations reddened by nebular continuum emission (e.g., Schaerer & de Barros 2009, 2010; Ono et al. 2010; Robertson et al. 2010), which in principle could allow relatively young, metal-poor populations with larger $\xi_{\text{ion}}$ to fall into the window of $\beta$ values found by Dunlop et al. (2012b). We find that for $f_{\text{esc}} \sim 0.2$, nebular models applied to young ($< 100$ Myr) constant star formation rate BC03 models are still marginally too blue ($\beta \sim -2.3$). Although more detailed modeling is always possible to explore the impact of nebular emission on $\xi_{\text{ion}}$, the uniformity observed by Dunlop et al. (2012b) in the average value of $\beta$ over a range in galaxy luminosities may argue against a diverse mixture of young and mature stellar populations in the current $z \approx 7$–8 samples. However, as Dunlop et al. (2012b) noted, a larger intrinsic scatter could be present in the UV slope distribution of the observed population but not yet detected. Similarly, top heavy initial mass function stellar populations with low metallicity, like the 1–100 $M_{\odot}$ Salpeter IMF models of Schaerer (2003) used by Bouwens et al. (2010) to explain the earlier HUDF09 data, are disfavored owing to their blue spectral slopes.

For reference, for conversion from UV luminosity spectral density to SFR, we note that for population ages $t > 10^8$ yr a constant SFR BC03 model with a Chabrier (2003) IMF and solar metallicity provides a 1500 Å luminosity spectral density of

$$L_{\text{UV}} \approx 1.25 \times 10^{28} \times \frac{\text{SFR}}{M_{\odot} \text{ yr}^{-1}} \text{ erg s}^{-1} \text{ Hz}^{-1}, \quad (13)$$

while, as noted by Madau et al. (1998), a comparable Salpeter (1955) model provides 64% of this UV luminosity. A very
4. ULTRAVIOLET LUMINOSITY DENSITY

In addition to constraints on the spectral energy distributions of high-redshift galaxies (Dunlop et al. 2012b), the UDF12 observations provide a critical determination of the luminosity function of star forming galaxies at redshifts 7 ≲ z ≲ 9. As described in Section 2, when calculating the comoving production rate \( n_{\text{ion}} \) of hydrogen-ionizing photons per unit volume (Equation (4)) the UV luminosity density \( \rho_{\text{UV}} \) provided by an integral of the galaxy luminosity function is required (Equation (5)). An accurate estimate of the \( \rho_{\text{UV}} \) provided by galaxies down to observed limits requires a careful analysis of star-forming galaxy samples at faint magnitudes. Using the UDF12 data, Schenker et al. (2012a) and McLure et al. (2012) have produced separate estimates of the \( z \sim 7–8 \) galaxy luminosity function for different sample selections (color-selected drop-out and spectral energy distribution-fitted samples, respectively). As we demonstrate, the UV luminosity densities computed from these separate luminosity functions are consistent within 1σ at \( z \sim 7 \) and in even closer agreement at \( z \sim 8 \). Further, McLure et al. (2012) have provided the first luminosity function estimates at \( z \sim 9 \). Combined, these star-forming galaxy luminosity function determination provide the required constraints on \( \rho_{\text{UV}} \) in the epoch \( z \gtrsim 7 \) when, as we show below, the ionization fraction of the IGM is likely changing rapidly.

Given the challenge of working at the limits of the observational capabilities of HST and the relatively small volumes probed by the UDF (with expected cosmic variance of \( \sim 30–40\% \) at redshifts \( z \sim 7–9 \); see Robertson 2010a, 2010b; Muñoz et al. 2010, and Section 4.2.3 of Schenker et al. 2012a), we anchor our constraints on the evolving UV luminosity density with precision determinations of the galaxy luminosity function at redshifts \( 4 \lesssim z \lesssim 6 \) by Bouwens et al. (2007).

To utilize as much information as possible about the luminosity function (LF) constraints at \( z \sim 4–9 \), we perform Bayesian inference to generate full posterior distributions of the galaxy luminosity functions at each redshift. To achieve this, we perform Schechter (1976) function parameter estimation at \( z \sim 4–9 \) using the stepwise maximum likelihood UV luminosity function constraints reported in Table 5 of Bouwens et al. (2007; for \( z \sim 4–6 \)) and Table 2 of McLure et al. (2012; for \( z \sim 7–8 \)) allowing all parameters (the luminosity function normalization \( \phi_{\star} \), the characteristic galaxy magnitude \( M_{\star} \), and the faint-end slope \( \alpha \) ) to vary. For these LF determinations, we assume Gaussian errors and a \( \chi^2 \) likelihood. For additional constraints at \( z \sim 7–8 \), we use the samples from the full posterior distributions of LF parameters determined by Schenker et al. (2012a), using their method for Bayesian inference of LF parameters discussed in their Section 4.2. Lastly, at redshift \( z \sim 9 \), we perform parameter estimation on \( \phi_{\star} \) given the stepwise maximum likelihood LF determination provided in Table 4 of McLure et al. (2012) while keeping \( M_{\star} \) and \( \alpha \) fixed at the best-fit \( z \sim 8 \) values reported by McLure et al. (2012). Again we assume Gaussian errors and a \( \chi^2 \) likelihood. The limited information available at \( z \sim 9 \) and our restricted fitting method at this redshift mean that the inferred allowed variation in the \( \rho_{\text{UV}}(z \sim 9) \) will be underestimated. However, we have checked that this restriction does not strongly influence our results presented in Section 5. In each case, our maximum likelihood luminosity function parameters are consistent within 1σ of the values originally reported by Bouwens et al. (2007) and McLure et al. (2012), and are of course identical in the case of the Schenker et al. (2012a) LFs.

Figure 2 shows the integrated UV luminosity density \( \rho_{\text{UV}} \) as a function of limiting magnitude for these galaxy luminosity function determinations at \( z \sim 5–8 \) (constraints at \( z \sim 4 \) and \( z \sim 9 \) are also used). For each redshift, we show the maximum likelihood \( \rho_{\text{UV}} \) (white lines) and the inner 68% variation in the marginalized \( \rho_{\text{UV}} \) (blue regions). Since the luminosity functions are steep (\( \alpha \sim -1.7 \)), the luminosity densities \( \rho_{\text{UV}} \) increase dramatically below the characteristic magnitude \( M_{\star} \) at each redshift, but especially at \( z \gtrsim 7 \). The total \( \rho_{\text{UV}} \) supplied by star-forming galaxies therefore strongly depends on the limiting magnitude adopted to limit the integral in Equation (5). The UDF12 campaign depth of \( M_{\text{UV}} < -17 \) provides \( \rho_{\text{UV}} \approx 10^{26} \text{ erg s}^{-1} \text{ Hz}^{-1} \text{ Mpc}^{-3} \) at \( z \sim 7 \), declining to \( \rho_{\text{UV}} \sim 3.2 \times 10^{25} \text{ erg s}^{-1} \text{ Hz}^{-1} \text{ Mpc}^{-3} \) at \( z \sim 8 \). To put these \( \rho_{\text{UV}} \) values in context, we also indicate the critical values of \( \rho_{\text{UV}} \) required to keep \( Q_{\text{HII}} = 0 \) in Equation (1) and maintain reionization (gray areas and dashed line; assuming case A recombination\(^{10} \) if \( f_{\text{esc}} = 0.2 \), log \( \xi_{\text{ion}} = 25.2 \log \text{erg}^{-1} \text{ Hz} \), and \( C_{\text{HII}} = 3 \). Under these reasonable assumptions, the currently observed galaxy population clearly is not abundant enough to maintain reionization at \( z \gtrsim 7 \). Understanding the role of galaxies in the reionization process will therefore likely require extrapolations to luminosities beyond even the UDF12 depth, and the constraints on the LF shape achieved by the UDF12 observations will be important for performing these extrapolations reliably. The extent of the extrapolation down the luminosity function required for matching the reionization constraints depends in detail on our assumptions for the escape fraction \( f_{\text{esc}} \) or the ionizing photon production rate per UV luminosity \( \xi_{\text{ion}} \) of galaxies. We emphasize that the critical ionizing photon production rate \( n_{\text{ion}} \) depends on the product \( n_{\text{ion}} = f_{\text{esc}} \xi_{\text{ion}} \rho_{\text{UV}} \), and will shift up or down proportionally to \( f_{\text{esc}} \xi_{\text{ion}} \) at fixed \( \rho_{\text{UV}} \). Similarly, the \( n_{\text{ion}} \) value that balances recombination is proportional to the clumping factor \( C_{\text{HII}} \), and variation in the clumping factor will also shift the required \( \rho_{\text{UV}} \) up or down.

4.1. UV Luminosity Density Likelihoods

We wish to use the evolving UV luminosity density \( \rho_{\text{UV}} \) to constrain the availability of ionizing photons \( n_{\text{ion}} \) as given in Equation (4). Given how significantly \( \rho_{\text{UV}} \) increases with the limiting absolute magnitude \( M_{\text{UV}} \), we must evaluate the full model presented in Section 2 for chosen values of \( M_{\text{UV}} \). We select \( M_{\text{UV}} = -17, M_{\text{UV}} = -13 \), and \( M_{\text{UV}} = -10 \) to provide a broad range of galaxy luminosities extending to extremely faint magnitudes. The observations probe to \( M_{\text{UV}} = -17 \), and this magnitude therefore serves as a natural limit. We consider limits as faint as \( M_{\text{UV}} = -10 \) as this magnitude may correspond to the minimum mass dark matter halo able to accrete gas from the photoheated intergalactic medium or the minimum mass dark matter halo able to retain its gas supply in the presence of supernova feedback. These scenarios have so far proven impossible to distinguish empirically (Muñoz & Loeb

---

\(^{10}\) When calculating whether the production rate of ionizing photons from galaxies can maintain the ionization fraction of the IGM near the end of reionization, an assumption of case A recombination is appropriate since recombinations to the hydrogen ground state largely do not help sustain the IGM ionization. For a detailed discussion, see Furlanetto & Oh (2005); Faucher-Giguère et al. (2009); Kuhlen & Faucher-Giguère (2012). We therefore adopt case A recombination in Figure 2. However, we assume case B recombination throughout the rest of the paper.
Figure 2. Constrained ultraviolet (UV) luminosity densities $\rho_{\text{UV}}$ as a function of limiting magnitude $M_{\text{UV}}$ and redshift $z$. Shown are the $z \sim 5–8$ maximum likelihood values of $\rho_{\text{UV}}$ vs. limiting magnitude calculated using Equation (5) (white lines), and the corresponding marginalized inner 68% credibility intervals for $\rho_{\text{UV}}(M_{\text{UV}})$ (blue regions). In each panel, we indicate with a dotted line the limiting depth of the luminosity function determinations. Also shown is the $\rho_{\text{UV}}$ required for galaxies to maintain a fully ionized universe assuming $\log \xi_{\text{ion}} = 25.2 \log \text{erg}^{-1} \text{Hz}, f_{\text{esc}} = 0.2, C_{\text{HI}} = 3$, and case A recombination (dashed lines and gray regions). We use Bayesian parameter estimation methods to determine the Schechter (1976) function parameter posterior distributions inferred from the stepwise maximum likelihood luminosity function (LF) data of Bouwens et al. (2007) at $z \sim 4–6$ and McLure et al. (2012) at $z \sim 7–8$. We also use the full posterior distribution sampling of the Schechter (1976) function parameters from the LF determination of Schenker et al. (2012a) to produce additional, independent constraints on $\rho_{\text{UV}}$ at $z \sim 7–8$. At $z \sim 9$ where the data are limited, we simply infer the LF normalization $\phi_\star$ keeping the characteristic magnitude $M_\star$ and faint-end slope $\alpha$ fixed at the $z \sim 8$ values determined by McLure et al. (2012) and expect the inferred possible variation in $\rho_{\text{UV}}(z \sim 9)$ to be somewhat underestimated.

(A color version of this figure is available in the online journal.)
To determine the required minimum luminosity of abundant star-forming galaxies to reionize the universe by \( z \sim 6 \).

Our chosen methodology is to use a simple parameterized model of the evolving UV luminosity density to calculate the redshift-dependent ionizing photon production rate density \( n_{\text{ion}} \), constrained to reproduce the UV luminosity density values reflected by the likelihood functions shown in Figure 3. The evolving \( n_{\text{ion}} \) with redshift is used to calculate the reionization history \( Q_{\text{HI}}(z) \) by integrating Equation (1). The corresponding Thomson optical depth is calculated using Equation (11) and then evaluated against the posterior distribution of \( \tau \) provided by the public nine-year WMAP MCMC. At each posterior sample evaluation, our method requires a full reconstruction of the reionization history and integration of the electron scattering optical depth and we have incorporated the reionization calculation into the MultiNest Bayesian inference software (Feroz & Hobson 2008; Feroz et al. 2009).

5.1. A Parameterized Model for the Evolving UV Luminosity Density

To infer constraints on the reionization process, we must adopt a flexible parameterized model for the evolving UV luminosity density. The model must account for the decline of \( \rho_{\text{UV}} \) apparent in Figures 2 and 3, without artificially extending the trend in \( \rho_{\text{UV}} \) at \( z \lesssim 6 \) to redshifts \( z \gtrsim 8 \). The rapid decline in \( \rho_{\text{UV}} \) between \( z \sim 4 \) and \( z \sim 5 \) suggests a trend of \( d \log \rho_{\text{UV}} / d z \sim -3 \), but the higher redshift values of \( \rho_{\text{UV}} \) flatten away from this trend, especially for faint limiting magnitudes. Beyond \( z \sim 10 \), we expect that some low-level UV luminosity density will be required to reproduce the Thomson optical depth, to varying degrees depending on the chosen limiting magnitude.

With these features in mind, we have tried a variety of parameterized models for \( \rho_{\text{UV}} \). We will present constraints using a three-parameter model given by

\[
\rho_{\text{UV}}(z) = \rho_{\text{UV}, z = 4} \left( \frac{z}{4} \right)^{-3} + \rho_{\text{UV}, z = 7} \left( \frac{z}{7} \right)^{\gamma}.
\]  

(14)

The low-redshift amplitude of this model is anchored by the UV luminosity density at \( z \sim 4 \), \( \rho_{\text{UV}, z = 4} \), with units of \( \text{s}^{-1} \text{Hz}^{-1} \text{Mpc}^{-3} \). The high-redshift evolution is determined by the normalization \( \rho_{\text{UV}, z = 7} \) at \( z \sim 7 \), provided in units of \( \text{s}^{-1} \text{Hz}^{-1} \text{Mpc}^{-3} \), and the power-law slope \( \gamma \). Using this model, we compute the evolving \( \rho_{\text{UV}}(z) \) and evaluate the parameter likelihoods as described immediately above.

We have examined other models, including general broken (double) power laws and low-redshift power laws with high-redshift constants or fixed slope power laws. Single power-law models tend to be dominated by the low-redshift decline in the \( \rho_{\text{UV}} \) and have difficulty reproducing the Thomson optical depth. Generic broken power-law models have a degeneracy between the low- and high-redshift evolution, even for fixed redshifts about which the power laws are defined, and are disfavored based on their Bayesian information relative to less complicated models that can also reproduce the \( \rho_{\text{UV}} \) constraints. The model in Equation (14) is therefore a good compromise between sufficient generality and resulting parameter degeneracies.

However, when using this model, we use a prior to limit \( \gamma < 0 \) to prevent increasing \( \rho_{\text{UV}} \) beyond \( z \sim 9 \). The best current constraints on the abundance of \( z \gtrsim 8.5 \) galaxies is from Ellis et al. (2013), where we demonstrated that the highest-redshift galaxies (with \( M_{\text{UV}} \lesssim -19 \)) continue the smooth decline in abundance found at slightly later times. Correspondingly,
Figure 3. Likelihood functions of the UV luminosity density \( \rho_{UV} \) for different limiting magnitudes and redshifts used to constrain the reionization history. Shown are the \( z \sim 5–8 \) marginalized posterior distributions for \( \rho_{UV} \) determined from Schechter (1976) function fits to luminosity function (LF) data, as reported in Figure 2, for limiting magnitudes of \( M_{UV} < -17 \) (red lines), \( M_{UV} < -13 \) (orange lines), and \( M_{UV} < -10 \) (blue lines). To infer the distributions at \( z \sim 4–9 \), we use the LF data of Bouwens et al. (2007) at \( z \sim 4–6 \), McLure et al. (2012) at \( z \sim 7–9 \), and Schenker et al. (2012a) at \( z \sim 7–8 \). In our posterior distributions for \( \rho_{UV}(z \sim 9) \), we keep the characteristic magnitude \( M_* \) and faint-end-slope \( \alpha \) values fixed at the \( z \sim 8 \) best-fit values reported by McLure et al. (2012) but expect the width of distribution to be somewhat overly narrow. These posterior distributions on \( \rho_{UV} \) are used as likelihood functions when fitting a parameterized model to the evolving UV luminosity density.

(A color version of this figure is available in the online journal.)
the constraint on \( \gamma \) amounts to a limit on introducing a new population of galaxies arising at \( z \gtrsim 9 \). The usefulness of this potentiality for the reionization of the universe has been noted elsewhere (e.g., Cen 2003; Alvarez et al. 2012). While imposing no constraint besides \( \gamma < 0 \), we typically find that nearly constant, low-level luminosity densities at high redshift are nonetheless favored (see below). Results for models that feature low-redshift power-law declines followed by low-level constant \( \rho_{\text{UV}} \) at high redshift will produce similar quantitative results. All parameterized models we have examined that feature a declining or constant \( \rho_{\text{UV}} \) and can reproduce the Thomson optical depth constraint produce similar results, and we conclude that our choice of the exact form of Equation (14) is not critical.

### 5.2. Reionization Constraints from Galaxies

Figure 4 shows constraints on the reionization process calculated using the model described in Section 2. We perform our Bayesian inference modeling assuming \( M_{\text{UV}} < -17 \) (close to the UDF12 limit at \( z \sim 8 \), the maximum likelihood model is shown as a dashed line in all panels), \( M_{\text{UV}} < -10 \) (an extremely faint limit, with the maximum likelihood model shown as a dotted line in all panels), and an intermediate limit \( M_{\text{UV}} < -13 \) (colored regions show 68% credibility regions, while the white lines indicate the maximum likelihood model). We now will discuss the UV luminosity density, stellar mass density, ionized filling fraction, and electron scattering optical depth results in turn.

The upper left panel shows parameterized models of the UV luminosity density (as given in Equation (14)), constrained by observations of the UV luminosity density (inferred from the measured luminosity functions, see Figures 2 and 3) integrated down to each limiting magnitude. The figure shows error bars to indicate the 68% credibility width of the posterior distributions of \( \rho_{\text{UV}} \) at redshifts \( z \sim 4-9 \) integrated to \( M_{\text{UV}} < -13 \), but the likelihood of each model is calculated using the full marginalized \( \rho_{\text{UV}} \) posterior distributions appropriate for its limiting magnitude. In each case, the \( \rho_{\text{UV}}(z) \) evolution matches well the constraints provided by the luminosity function extrapolations, which owes to the well-defined progression of declining \( \rho_{\text{UV}} \) with redshift inferred from the UDF12 and earlier data sets. For reference, the maximum likelihood values for the parameters of Equation (14) for \( M_{\text{UV}} < -13 \) are \( \log \rho_{\text{UV},z=4} = 26.50 \log \text{erg} \, s^{-1} \, \text{Hz}^{-1} \, \text{Mpc}^{-3} \), \( \log \rho_{\text{UV},z=7} = 25.82 \log \text{erg} \, s^{-1} \, \text{Hz}^{-1} \, \text{Mpc}^{-3} \), and \( \gamma = -0.003 \).

What drives the constraints on \( \rho_{\text{UV}} \) for these limiting magnitudes? Some tension exists at high redshift, as the models prefer a relatively flat \( \rho_{\text{UV}}(z) \) beyond the current reach of the data. In each case, the maximum likelihood models become flat at high redshift and reflect the need for continued star formation at high redshift to sustain a low-level of partial IGM ionization. To better answer this question, we have to calculate the full stellar mass density evolutions, reionization histories, and Thomson optical depths of each model.

The lower left panel shows how the models compare to the stellar mass densities extrapolated from the results by Stark et al. (2013), using the method described in Section 2. The error bars in the figure reflect the stellar mass densities extrapolated for contributions from galaxies with \( M_{\text{UV}} < -13 \), but the appropriately extrapolated mass densities are used for each model. The error bars reflect bootstrap-calculated uncertainties that account for statistically possible variations in the best-fit stellar mass–UV luminosity relation given by Equation (8), and are \( \sigma \approx 0.3 \) dex at \( z \approx 7 \). To balance the relative constraint from the stellar mass density evolution with the single optical depth constraint (below), we assign the likelihood contributions of the stellar mass density and Thomson optical depth equal weight. The stellar mass densities calculated from the models evolve near the 1σ upper limits of the extrapolated constraints, again reflecting the need for continued star formation to sustain a low-level of IGM ionization.\(^{11} \)

Assuming a ratio of Lyman continuum photon production rate to UV luminosity \( \log \xi_{\text{ion}} = 25.2 \log \text{erg}^{-1} \, \text{Hz} \) for individual sources consistent with UV slopes measured from the UDF12 data (Dunlop et al. 2012b), an ionizing photon escape fraction \( f_{\text{esc}} = 0.2 \), and an intergalactic medium clumping factor of \( C_{\text{HI}} = 3 \), the reionization history \( Q_{\text{HI}}(z) \) produced by the evolving \( \rho_{\text{UV}} \) can be calculated by integrating Equation (1) and is shown in the upper right panel of Figure 4. We find that the currently observed galaxy population at magnitudes brighter than \( M_{\text{UV}} < -17 \) (dashed line) can only manage to reionize fully the universe at late times \( z \sim 5 \), with the IGM 50% ionized by \( z \sim 6 \) and \(<5\% \) ionized at \( z \sim 12 \). Contributions from galaxies with \( M_{\text{UV}} < -13 \) reionize the universe just after \( z \sim 6 \), in agreement with a host of additional constraints on the evolving ionized fraction (see Section 6 below) and as suggested by some previous analyses (e.g., Salvaterra et al. 2011). These galaxies can sustain a \( \sim 50\% \) ionized fraction at \( z \sim 7.5 \), continuing to \( \sim 12-15\% \) at redshift \( z \sim 12 \). Integrating further down to \( M_{\text{UV}} < -10 \) produces maximum likelihood models that reionize the universe slightly earlier.

The Thomson optical depths resulting from the reionization histories can be determined by evaluating Equation (11). To reproduce the nine-year WMAP \( \tau \) values, most models display low levels of UV luminosity density that persist to high redshift. Even maintaining a flat \( \rho_{\text{UV}} \) at the maximum level allowed by the luminosity density constraints at redshifts \( z \lesssim 9 \), as the maximum likelihood models do, the optical depth just can be reproduced. When considering only the currently observed population \( M_{\text{UV}} < -17 \), the UV luminosity density would need to increase toward higher \( z > 10 \) redshifts for the universe to be fully reionized by redshift \( z \sim 6 \) and the Thomson optical depth to be reproduced.

We remind the reader that while the exact results for, e.g., the \( Q_{\text{HI}} \) evolution of course depends on the choices for the escape fraction \( f_{\text{esc}} \) or the ionizing photon production rate \( \xi_{\text{ion}} \). If \( f_{\text{esc}} \) or \( \xi_{\text{ion}} \) are lowered, then the evolution of \( Q_{\text{HI}} \) is shifted toward lower redshift. For instance, with all other assumptions fixed, we find that complete reionization is shifted to \( z \sim 5 \) for \( f_{\text{esc}} = 0.1 \) and \( z \sim 4.75 \) for \( \log \xi_{\text{ion}} = 25.0 \log \text{erg}^{-1} \, \text{Hz} \). Complete reionization can also be made earlier by choosing a smaller \( C_{\text{HI}} \) or delayed by choosing a larger \( C_{\text{HI}} \).

Given the above results, we conclude that under our assumptions (e.g., \( f_{\text{esc}} = 0.2 \) and \( C_{\text{HI}} \approx 3 \)) galaxies currently observed down to the limiting magnitudes of deep high-redshift surveys (e.g., UDF12) do not reionize the universe alone, and to simultaneously reproduce the \( \rho_{\text{UV}} \) constraints, the \( \tau \) constraint, and to reionize the universe by \( z \sim 6 \) requires yet fainter populations. This conclusion is a ramification of the UDF12 UV spectral slope constraints by Dunlop et al. (2012b), which eliminate the possibility that increased Lyman continuum emission by metal-poor populations could have produced reionization at \( z > 6 \).

\(^{11}\) We note that if we ignore the electron scattering optical depth constraint, the other data sets favor a UV luminosity density that declines more rapidly at high redshift than does our maximum likelihood model calculated including all the constraints. However, the UV luminosity density parameters in Equation (14) remain similar. Excluding the stellar mass density constraint has almost no effect on the maximum likelihood parameters inferred for the model.
Figure 4. Joint constraints on the reionization history, assuming ionizing photon contributions from galaxies with $M_{\text{UV}} < -17$ (maximum likelihood model shown as dashed line in all panels), $M_{\text{UV}} < -10$ (maximum likelihood model shown as dotted line in all panels), and $M_{\text{UV}} < -13$ (maximum likelihood model shown as white line in all panels; 68% credibility regions shown as colored areas). We use the posterior distributions for $\rho_{\text{UV}}$ with redshift shown in Figure 3, extrapolated stellar mass density constraints, and the posterior distribution on the electron scattering optical depth (Hinshaw et al. 2012) as likelihood functions to constrain the simple parameterized model for the evolving UV luminosity density given by Equation (14) at redshifts $z \gtrsim 4$. The constrained evolution of $\rho_{\text{UV}}$ is shown in the upper left panel (error bars indicate the $\rho_{\text{UV}}$ constraints for $M_{\text{UV}} < -13$, but each model uses the appropriate constraints). From $\rho_{\text{UV}}(z)$, we can simply integrate with redshift to determine the stellar mass densities (bottom left panel; data points with error bars indicate extrapolations of the Stark et al. (2013) stellar mass densities to $M_{\text{UV}} < -13$, but all models use the appropriate constraints). The models tend to exceed slightly the stellar mass densities at the highest redshifts ($z \sim 7$), a result driven by the constraint on the electron scattering optical depth. By assuming the well-motivated values of the ratio of Lyman continuum photon production rate to UV luminosity $\log \xi_{\text{ion}} = 25.2 \log \text{erg}^{-1} \text{Hz}$ for individual sources, an ionizing photon escape fraction $f_{\text{esc}} = 0.2$, and an intergalactic medium clumping factor of $C_{\text{HI}} = 3$, the reionization history $Q_{\text{HII}}$ calculated by integrating Equation (1) is shown in the upper right panel. Integrating the reionization history provides the electron scattering optical depth (lower right panel, nine-year WMAP constraint indicated as the gray region).

(A color version of this figure is available in the online journal.)

(e.g., Robertson et al. 2010). However, too much additional star formation beyond the $M_{\text{UV}} < -13$ models shown in Figure 4 will begin to exceed the stellar mass density constraints, depending on $f_{\text{esc}}$. It is therefore interesting to know whether the $M_{\text{UV}} < -13$ models that satisfy the $\rho_{\text{UV}}$, $\rho_*$, and $\tau$ constraints also satisfy other external constraints on the reionization process, and we now turn to such an analysis.

6. COMPARISON TO OTHER PROBES OF THE IONIZED FRACTION

In this section, we will collect constraints on the IGM neutral fraction from the literature and compare them to the evolution of this quantity in our models based on the UDF12 data. These constraints come from a wide variety of astrophysical
measurements, but all are subject to substantial systematic or modeling uncertainties, about which we will comment below. We show the full set in Figure 5, along with a comparison to our model histories. We will first briefly discuss these constraints and then how our model histories fare in comparison to them.

6.1. The Lyα Forest

The best known Lyα forest constraints come from Fan et al. (2006b), who measured the effective optical depth evolution along lines of sight taken from Sloan Digital Sky Survey (SDSS; including both Lyα and higher-order transitions, where available). Those authors then made assumptions about the IGM temperature and the distribution of density inhomogeneities throughout the universe to infer the evolution of the neutral fraction (these assumptions are necessary for comparing the higher-order transitions to Lyα as well, because those transitions sample different parts of the IGM). The corresponding limits on the neutral fraction according to their model are shown by the filled triangles in Figure 5.

The original data here are the transmission measurements in the different transitions. Transforming those into constraints on the ionized fraction requires a model that: (1) predicts the temperature evolution of the IGM (Hui & Haiman 2003; Trac et al. 2008; Furlanetto & Oh 2009); (2) describes the distribution of gas densities in the IGM (Miralda-Escudé et al. 2000; Bolton & Becker 2009); (3) accounts for spatial structure in the averaged transmission measurements (Lidz et al. 2006); and (4) predicts the topology of ionized and neutral regions at the tail end of reionization (Furlanetto et al. 2004b; Choudhury et al. 2009). These are all difficult, and the Fan et al. (2006b) constraints—based upon a simple semi-analytic model for the IGM structure—can be evaded in a number of ways. In particular, their model explicitly ignores the possibility that $Q_{\text{HII}} < 1$, working only with the residual neutral gas inside a mostly ionized medium.

Unsurprisingly, our models do not match these Lyα forest measurements very well. The crude approach of Equation (1) fails to address effects from the detailed density structure of the IGM on the evolution of the mean ionization fraction near the end of the reionization process. Our model is therefore not sufficient to model adequately the tail end of reionization, and only more comprehensive models that account for both radiative transfer effects and the details of IGM structure will realistically model these data at $z < 6$.

More useful to us is a (nearly) model-independent upper limit on the neutral fraction provided by simply counting the dark pixels in the spectra (Mesinger 2010). McGregor et al. (2011) present several different sets of constraints, depending on how one defines “dark” and whether one uses a small number of very deep spectra (with a clearer meaning to the dark pixels but more cosmic variance) versus a larger set of shallower spectra. Their strongest constraints are roughly $1 - Q_{\text{HII}} < 0.2$ at $z = 5.5$ and $1 - Q_{\text{HII}} < 0.5$ at $z = 6$, shown by the open triangles in Figure 5. Interestingly, this model-independent approach permits rather late reionization.

6.2. Ionizing Background

Another use of the Lyα forest is to measure the ionizing background and thereby constrain the emissivity $\epsilon$ of galaxies: the ionization rate $\Gamma \propto \ell \epsilon$, where $\lambda$ is the Lyman continuum mean free path. Bolton & Haehnelt (2007b) attempted such a measurement at $z > 5$. The method is difficult as it involves interpretation of spectra near the saturation limit of the forest. Nonetheless, the Bolton & Haehnelt (2007b) analysis shows that the ionizing background falls by about a factor of 10 from $z \sim 3$ to $z \sim 6$ (though see McQuinn et al. 2011). The resulting comoving emissivity is roughly the same as at $z \sim 2$, corresponding to 1.5–3 photons per hydrogen atom over the age of the Universe (see also Haardt & Madau 2012).

Additional detailed constraints were derived by Faucher-Giguère et al. (2008), who used quasar spectra at $2 \lesssim z \lesssim 4$ to infer a photoionization rate for intergalactic hydrogen. Combining these measurements with the previous work by Bolton & Haehnelt (2007b) and estimates of the intergalactic mean free path of Lyman continuum photons (Prochaska et al. 2009; Songaila & Cowie 2010), Kuhlen & Faucher-Giguère (2012) calculated constraints on the comoving ionizing photon production rate. These inferred values of $\log n_{\text{ion}} < 51 \log s^{-1} \text{Mpc}^{-3}$ at $z \sim 2$–6 are lower than those produced by naively extrapolating typical models of the evolving high-redshift UV luminosity density that satisfy reionization constraints. To satisfy both the low-redshift IGM emissivity constraints and the reionization era constraints then available, Kuhlen & Faucher-Giguère (2012)
posited an evolving escape fraction

\[ f_{\text{esc}}(z) = f_0 \times [(1 + z)/5]^\kappa. \]  

(15)

If the power-law slope \( \kappa \) is large enough, then the IGM emissivity constraints at \( z < 6 \) can be satisfied with a low \( f_0 \) while still reionizing the universe by \( z \sim 6 \) and matching previous WMAP constraints on the electron scattering optical depth. Other previous analyses have emphasized similar needs for an evolving escape fraction (e.g., Ferrara & Loeb 2013; Mitra et al. 2013).

To study the effects of including the IGM emissivity constraints by permitting an evolving \( f_{\text{esc}} \), we repeat our calculations in Section 5, additionally allowing an escape fraction given by Equation (15) with varying \( f_0 \) and \( \kappa \) (and maximum escape fraction \( f_{\text{max}} = 1 \)). With a limiting magnitude \( M_{\text{UV}} < -13 \), and utilizing the updated constraints from UDF12 and WMAP, we find maximum likelihood values \( f_0 = 0.054 \) and \( \kappa = 2.4 \) entirely consistent with the results of Kuhlen & Faucher-Giguère (2012, see their Figure 7). When allowing for this evolving \( f_{\text{esc}} \) (with \( f_{\text{max}} = 1 \)), we sensibly find that the need for low-level star formation to satisfy reionization constraints is reduced (the maximum likelihood model has a high-redshift luminosity density evolution. The need for a low-level of reionization process than the constant model described in Section 5 can therefore also satisfy the low-redshift IGM emissivity constraints without assuming an escape fraction of \( f_{\text{esc}} \sim 1 \) at high redshifts. While the evolving covering fraction in galaxy spectra (Jones et al. 2012) provides additional observational support for a possible evolution in the escape fraction at \( z \lesssim 5 \), such empirical support for evolving \( f_{\text{esc}} \) does not yet exist at \( z \gtrsim 5 \).

6.3. The Lyα Damping Wing

Another use of the Lyα line is to measure precisely the shape of the red damping wing of the line: the IGM absorption is so optically thick that the shape of this red absorption wing depends upon the mean neutral fraction in the IGM (Miralda-Escudé 1998), though the interpretation depends upon the morphology of the reionization process, leading to large intrinsic scatter and biases (McQuinn et al. 2008; Mesinger & Furlanetto 2008a). Such an experiment requires a deep spectrum of a bright source in order to identify the damping wing. One possibility is a gamma-ray burst, which has an intrinsic power-law spectrum, making it relatively easy to map the shape of a damping wing. The disadvantage of these sources is that (at lower redshift) they almost always have damped Lyα (DLA) absorption from the host galaxy, which must be disentangled from any IGM signal (Chen et al. 2007).

To date, the best example of such a source is GRB050904 at \( z = 6.3 \), which received rapid follow-up and produced a high signal-to-noise spectrum (Totani et al. 2006). McQuinn et al. (2008) studied this spectrum in light of patchy reionization models. Because it has intrinsic DLA absorption, the constraints are relatively weak: they disfavor a fully neutral IGM but allow \( Q_{\text{HII}} \sim 0.5 \). We show this measurement with the open circle in Figure 5.

Quasars provide a second possible set of sources. These are much easier to find but suffer from complications due to patchy reionization near the Lyα line. Schroeder et al. (2013) have modeled the spectra of three SDSS quasars in the range \( z = 6.24–6.42 \) and found that all three are best fit if a damping wing is present (see also Mesinger & Haiman 2004). Any absorption wing with no DLA absorption, the constraints are relatively weak: they disfavor a fully neutral IGM but allow \( Q_{\text{HII}} \sim 0.5 \). We show this point as the open square in Figure 5. This conclusion is predicated on accurate modeling of the morphology of reionization around quasars and the distribution of strong IGM absorbers at the end of reionization.

6.4. The Near Zones of Bright Quasars

Any ionizing source that turns on inside a mostly neutral medium will carve out an HII region whose extent depends upon the total fluence of ionizing photons from the source. If one can measure (or guess) this fluence, the extent of the ionized bubble then offers a constraint on the original neutral fraction of the medium. This is, of course, a difficult proposition, as the extremely large Lyα optical depth implies that the spectrum may go dark even if the region is still highly ionized: in this case, you find only a lower limit to the size of the near zone (Bolton & Haehnelt 2007a).

Carilli et al. (2010) examined the trends of near-zone sizes in SDSS quasars from \( z = 5.8–6.4 \). The sample shows a clear trend reionization completes within \( \Delta z \approx 0.1 \) of the redshift suggested by the maximum likelihood constant \( f_{\text{esc}} \) model of Section 5.
of decreasing size with increasing redshift (after compensation for varying luminosities) by about a factor of two over that redshift range. Under the assumption that near zones correspond to ionized bubbles in a (partially) neutral medium, the volume \( V \propto (1 - Q_{\text{HI}})^{-1} \), or, in terms of the radius, \( R_{\text{nz}}^{-3} \propto (1 - Q_{\text{HI}}) \). In that case, a twofold decrease in size corresponds to an order of magnitude increase in the neutral fraction. However, if the Fan et al. (2006b) \( \text{Ly}\alpha \) forest measurements are correct, then the neutral fraction at \( z \approx 5.8 \) is so small that the zones are very unlikely to be in this regime. In that case, the trend in sizes cannot be directly transformed into a constraint on the filling factor of ionized gas. We therefore do not show this constraint in Figure 5, as its interpretation is unclear.

The recently discovered \( z = 7.1 \) quasar has a very small near-zone (Mortlock et al. 2011). Bolton et al. (2011) used a numerical simulation to analyze it in detail. They concluded the curves is entirely arbitrary (as is the shape: there is absolutely no reason to expect a linear correlation between redshift and neutral fraction). They simply offer a rough guide to the maximum duration over which substantial patchiness can persist.

### 6.5. The Kinetic Sunyaev–Zel’dovich Effect

Recent small-scale temperature measurements have begun to constrain the contribution of patchy reionization to the kinetic Sunyaev–Zel’dovich (kSZ) effect, which is generated by CMB photons scattering off coherent large-scale velocities in the IGM. These scatterings typically cancel (because any redshift gained from scattering off of gas falling into a potential well is canceled by scattering off gas on the other side), but during reionization modulation by the ionization field can prevent such cancellation (Gruzinov & Hu 1998; Knox et al. 1998). There is also a contribution from nonlinear evolution, see Ostriker & Vishniac (1986). Both the Atacama Cosmology Telescope (ACT) and the South Pole Telescope (SPT) have placed upper limits on this signal (Dunkley et al. 2011; Reichardt et al. 2012).

Because the patchiness and inhomogeneity of the process induce this signal, the kSZ signal grows so long as this patchy contribution persists. As a result, it essentially constrains the duration of reionization. Using SPT data, Zahn et al. (2012) claim a limit of \( \Delta \zeta < 7.2 \) (where \( \Delta \zeta \) is the redshift difference between \( Q_{\text{HI}} = 0.2 \) and \( Q_{\text{HI}} = 0.99 \)) at 95% confidence. The primary limiting factor here is a potential correlation between the thermal Sunyaev–Zel’dovich effect and the cosmic infrared background, which pollutes the kSZ signal. If that possibility is ignored, then the limit on the duration falls to \( \Delta \zeta < 4.4 \). Mesinger et al. (2012) found similar limits from ACT data. They showed that the limit without a correlation is difficult to reconcile with the usual models of reionization. Intensive efforts are now underway to measure the correlation.

We show two examples of the slowest possible evolution allowed by these constraints (allowing for a correlation) with the straight dashed lines in Figure 5. Note that the timing of these curves is entirely arbitrary (as is the shape: there is absolutely no reason to expect a linear correlation between redshift and neutral fraction). The primary difficulty with measurements of the evolution of the Ly\( \alpha \) emitter number density is that the overall galaxy population is also evolving, and it can be difficult to determine if evolution in the number density is due to changes in the IGM properties or in the galaxy population. An alternate approach is therefore to select a galaxy sample independently of the Ly\( \alpha \) line (or at least as independently as possible) and determine how the fraction of these galaxies with strong Ly\( \alpha \) lines evolves (Stark et al. 2010). Such a sample is available through broadband Lyman break searches with HST and Subaru. Several groups have performed these searches to \( z \approx 8 \) (Fontana et al. 2010; Pentericci et al. 2011; Schenker et al. 2012b; Ono, S. et al. 2012b) and found that although the fraction of Ly\( \alpha \) emitters increases slightly for samples of similar UV luminosity from \( z \approx 3-6 \), there is a marked decline beyond \( z \approx 6.5 \) (see also Treu et al. 2012). This decline could still be due to evolutionary processes within the population (e.g., dust content, see Dayal & Ferrara 2012), but both the rapidity of the possible evolution and its reversal from trends now well established at lower redshift make this unlikely. Assuming that this decline can be attributed to the increasing neutrality of the IGM, it requires \( Q_{\text{HI}} \lesssim 0.5 \) (McQuinn et al. 2007; Mesinger & Furlanetto 2008b; Dijkstra et al. 2011). We show this constraint with the filled pentagon in Figure 5.

There is one more signature of reionization in the Ly\( \alpha \) lines of galaxies. A partially neutral IGM does not extinguish these lines uniformly: galaxies inside of very large ionized bubbles suffer little absorption, while isolated galaxies disappear even when \( Q_{\text{HI}} \) is large. This manifests as a change in the apparent clustering of the galaxies, which is attractive because such a strong change is difficult to mimic with baryonic processes within and around galaxies (Furlanetto et al. 2006; McQuinn et al. 2007; Mesinger & Furlanetto 2008b). Clustering is a much more difficult measurement than the number density, requiring...
a large number of sources. It is not yet possible with the Lyα line sources at \(z \approx 7\), but at \(z \approx 6.6\) there is no evidence for an anomalous increase in clustering (McQuinn et al. 2007; Ouchi et al. 2010), indicating \(\Omega_{\text{HI}} \gtrsim 0.5\) at that time. We show this constraint with the filled diamond in Figure 5.

### 6.7. Comparison to Our Models

Figure 5 also shows the reionization history in our preferred model, with the associated confidence intervals, that extrapolates the observed luminosity function to \(M_{\text{UV}} = -13\). Amazingly, this straightforward model obeys all the constraints we have listed in this section, with the exception of the Fan et al. (2006b) Lyα forest measurements. However, we remind the reader that our crude reionization model fails at very small neutral fractions because it does not properly account for the high gas clumping in dense systems near galaxies, so we do not regard this apparent disagreement as worrisome to any degree.

It is worth considering the behavior of this model in some detail. A brief examination of the data points reveals that the most interesting limits come from the Lyα lines inside of galaxies (the filled pentagon, from spectroscopic follow-up of Lyman break galaxies, and the open pentagons, from direct narrowband detection of galaxies at \(z \approx 6.6\) and 7). These must be relatively high neutral fractions at \(z \approx 7\) in order for the IGM to affect the observed abundance significantly; the model shown here just barely satisfies the constraints. In a model in which we integrate the luminosity function to fainter magnitudes (e.g., \(M_{\text{UV}} < -10\), dotted line), the ionized fraction is somewhat higher at this time and may prevent the lines from being significantly extinguished, while a model with the minimum luminosity closer to the observed limit (e.g., \(M_{\text{UV}} < -17\), dashed line) reionizes the universe so late that the emitter population at \(z \approx 6.6\) should have been measurably reduced.

Clearly, improvements in the measured abundance of strong line emitters at this epoch (perhaps with new multi-object infrared spectrographs, like LUCI on LBT or MOSFIRE on Keck, or with new wide-field survey cameras, like HyperSuprimeCam) will be very important for distinguishing viable reionization histories. Equally important will be improvements in the modeling of the decline in the Lyα line emitters, as a number of factors both outside (the morphology of reionization, resonant absorption near the source galaxies, and absorption from dense IGM structures) and inside galaxies (dust absorption, emission geometry, and winds) all affect the detailed interpretation of the raw measurements (e.g., Santos 2004; Dijkstra et al. 2011; Bolton & Haehnelt 2013).

In order to have a relatively high neutral fraction at \(z \approx 7\), a plausible reionization history cannot complete the process by \(z \approx 6.4\) (to which the most distant Lyα forest spectrum currently extends), unless either (1) the Lyman continuum luminosity of galaxies, per unit 1500 Å luminosity, evolves rapidly over that interval, (2) the escape fraction \(f_{\text{esc}}\) increases rapidly toward lower redshifts, or (3) the abundance of galaxies below \(M_{\text{UV}} \approx -17\) evolves rapidly. Otherwise, the UDF12 luminosity functions have sufficient precision to fix the shape of the \(Q_{\text{HI}}(z)\) curve over this interval (indeed, to \(z \approx 8\)), and as shown in Figure 5, the slope is relatively shallow. Indeed, in our best-fit model the universe still has \(1.0 - Q_{\text{HI}} \approx 0.1\) at \(z \approx 6\). This suggests intensifying searches for the last neutral regions in the IGM at this (relatively) accessible epoch.

Although reionization ends rather late in this best-fit model, it still satisfies the WMAP optical depth constraint (at 1σ) thanks to a long tail of low-level star formation out to very high redshifts, as suggested by Ellis et al. (2013), although the agreement is much easier if the WMAP value turns out to be somewhat high. This implies that the kSZ signal should have a reasonably large amount of power. Formally, our best-fit model has \(\Delta z \sim 5\), according to the definition of Zahn et al. (2012), which is within the range that can be constrained if the thermal Sunyaev–Zel’dovich contamination can be sorted out. We also note that the WMAP results (Hinshaw et al. 2012) indicate that when combining the broadest array of available data sets, the best-fit electron scattering optical depth lowers by \(\sim 5\%\) to \(\tau \approx 0.08\).

In summary, we have shown that the UDF12 measurements allow a model of star formation during the cosmic dawn that satisfies all available constraints on the galaxy populations and IGM ionization history, with reasonable extrapolation to fainter systems and no assumptions about high-redshift evolution in the parameters of star formation or UV photon production and escape. Of course, this is not to say such evolution cannot occur (see Kuhlen & Faucher-Giguère 2012, Alvarez et al. 2012, and our Section 6.2 for examples in which it does), but it does not appear to be essential.

### 7. Summary

The UDF12 campaign, a 128-orbit HST program (GO 12498, PI: R. Ellis, as described in Ellis et al. 2013 and Koekemoer et al. 2013), has acquired the deepest infrared WFC3/IR images ever taken with HST. These observations have enabled the first identification of galaxies at \(8.5 \leq z \leq 12\) in the Ultra Deep Field (Ellis et al. 2013), newly accurate luminosity function determinations at redshifts \(7 \approx 7–8\) (Schenker et al. 2012a; McLure et al. 2012), robust determinations of the ultraviolet spectral slopes of galaxies at \(z \approx 7–8\) (Dunlop et al. 2012b), and the first estimates of the luminosity function and spectral slopes at \(z \approx 9\) (McLure et al. 2012; Dunlop et al. 2012b). Synthesizing these constraints on high-redshift galaxy populations with the recent nine-year WMAP constraints on the electron scattering optical depth generated by ionized cosmic hydrogen (Hinshaw et al. 2012) and previous determinations of the galaxy luminosity function at redshifts \(4 \leq z \leq 6\) (Bouwens et al. 2007), we infer constraints on the reionization history of the universe.

First, we use the UV spectral slope \(\beta = -2\) of high-redshift galaxies measured by Dunlop et al. (2012b) to constrain the available Bruzual & Charlot (2003) stellar population models consistent with the spectral character of galaxies at \(z \approx 7–9\). These models motivate the adoption of a Lyman continuum photon production rate per unit UV luminosity spectral density \(\xi_{\text{ion}} = 25.2 \log \text{erg}^{-1} \text{Hz}\); the data do not favor a luminosity-dependent variation in the efficiency of Lyman continuum photon production. With this value of \(\xi_{\text{ion}}\) for high-redshift galaxies, and under reasonable assumptions for the Lyman continuum photon escape fraction from galaxies and the clumping factor of intergalactic gas (as motivated by cosmological simulations), we find that the currently observed galaxy population accessible to the limiting depth of UDF12 (\(M_{\text{UV}} < -17\) to \(z \approx 8\)) cannot simultaneously reionize the universe by \(z \approx 6\) and reproduce the Thomson optical depth \(\tau\) unless the abundance of star-forming galaxies or the ionizing photon escape fraction increases beyond redshift \(z \approx 12\) from what is currently observed.

If we utilize constraints on the evolving galaxy luminosity function at redshifts \(4 \leq z \leq 9\) to extrapolate down in luminosity, we find that the tension between the declining abundance of star-forming galaxies and their stellar mass density...
with redshift, the observed requirement to reionize the universe by $z \sim 6$, and reproducing the large electron scattering optical depth $\tau \approx 0.084$ is largely fulfilled if the galaxy population continues down to $M_{UV} < -13$ and the epoch of galaxy formation continues to $z \sim 12$. Given the first identification of a $z \sim 12$ candidate galaxy by the UDF12 program, the prospect for high-redshift galaxies to reionize the universe is positive provided that the epoch of galaxy formation extends to $z \gtrsim 12$. Further observations by HST (e.g., the “Frontier Fields”) and, ultimately, the James Webb Space Telescope will be required to answer these questions more definitively.

We thank Gary Hinshaw and David Larson for pointing us to the MCMC chains used in inferring the WMAP nine-year cosmological constraints.
