Emerging Use of Ultra-High-Field 7T MRI in the Study of Intracranial Vascularity: State of the Field and Future Directions

J.W. Rutland, B.N. Delman, C.M. Gill, C. Zhu, R.K. Shrivastava, and P. Balchandani

ABSTRACT

SUMMARY: Cerebrovascular disease is a major source of mortality that commonly requires neurosurgical intervention. MR imaging is the preferred technique for imaging cerebrovascular structures, as well as regions of pathology that include microbleeds and ischemia. Advanced MR imaging sequences such as time-of-flight, susceptibility-weighted imaging, and 3D T2-weighted sequences have demonstrated excellent depiction of arterial and venous structures with and without contrast administration. While the advantages of 3T compared with 1.5T have been described, the role of ultra-high-field (7T) MR imaging in neurovascular imaging remains poorly understood. In the present review, we examine emerging neurosurgical applications of 7T MR imaging in vascular imaging of diverse conditions and discuss current limitations and future directions for this technique.

ABBREVIATION: UHF = ultra-high-field

MR imaging at 7T is particularly beneficial to vascular imaging techniques. TOF angiography benefits from increased SNR and lengthening T1s at higher field strengths, allowing more effective tagging of flowing spins.1,2 SWI also benefits from increased SNR as well as the enhanced sensitivity of susceptibility effects at 7T.3-4 Vessel wall imaging techniques benefit in the same way as other T2-weighted sequences from increased SNR, allowing depiction of smaller structures such as the thickness of the vessel wall. MPRAGE also benefits from increased SNR, permitting smaller voxel volumes and higher-resolution imaging. The benefits along with the limitations of 7T MR imaging, including increased B0 and B1 inhomogeneity artifacts, should be examined to clarify the role of this emerging technology in the field of cerebrovascular imaging.

Here, we focus on the vascular components of neurologic protocols at 7T and their value to better diagnose and plan surgery, predict prognosis, and monitor treatment. We cover current primary neurosurgical applications for 7T vascular imaging and discuss areas for future development.

CLINICAL APPLICATIONS

Intracranial Tumors

Glioma. High-grade gliomas are among the most vascularized malignant neoplasms, and angiogenesis is critical to their growth.5,6 There is interest in quantifying micro- and macrovascular properties of gliomas to predict tumor grade and better characterize microscopic infiltration (On-line Table 1). Moenninghoff et al7 found increasing microvascularity from low- to high-grade gliomas using 7T T2* MR imaging; 7T depicted susceptibility patterns that indicated microvascularity in 53% of patients compared with 33% using 1.5T MR imaging. While the authors attribute this difference to increased sensitivity of susceptibility contrast at 7T, there is a possibility that some of these findings could be false-positives due to increased conspicuity of imaging features imparted by a higher SNR at an ultra-high-field (UHF) strength. Differentiation of these potential false-positives from true clinical findings is an important area of future investigation.7 Paek et al8 also found that T2* 7T MR imaging provided superior depiction of glioma microvascularity compared with 1.5T MR imaging and reported gliomas with high intratumoral vasculature in 33.3% of cases at 7T compared with 12.5% at 1.5T. Christoforidis et al9 used UHF gradient-echo MR imaging to demonstrate that tumoral pseudoblush...
correlated histologically with foci of increased microvascularity and overall tumor grade. These studies suggest that 7T MR imaging may be useful in the noninvasive evaluation of tumor features that contribute to the World Health Organization grade, including microvascularity and necrosis, and could facilitate early stratification and risk assessment for patients with gliomas. However, multiple authors have also conceded that susceptibility artifacts near large air-tissue interfaces and the skull base could compromise the utility of 7T in some patients.  

MR imaging at 7T may also assist in identifying parenchymal areas with an increased likelihood of microscopic high-grade glioma infiltration, which is challenging at clinical field strengths and important for determining resection margins. Various imaging metrics, including those based on DWI, have been used to identify white matter infiltration by gliomas that cannot be resolved at lower field strengths. In addition, 7T SWI has proved superior in the delineation of venous structures. Grabner et al found that 7T SWI correctly predicted high-grade gliomas in 23.8% more cases than 3T SWI, suggesting that vasculature quantification at 7T may offer increased sensitivity for imaging glioblastoma multiforme preoperatively. These results concur with those of Moenninghoff et al who also found higher tumor microvascularity in high-grade gliomas compared with low-grade lesions using 7T SWI.  

Clinical applications of TOF angiography have been somewhat limited due to low spatial resolution attained at 1.5T and 3T; therefore, DSA remains the criterion standard angiographic technique. However, detectability of arterial structures using 7T TOF could be useful in noninvasive characterization of intratumoral vasculature. Advantages of TOF at 7T include increased SNR, longer T1 relaxation times augmenting vessel-tissue contrast, and inherently hyperintense arterial vasculature at higher field strengths overall. Radbruch et al demonstrated the feasibility of 7T TOF in imaging intratumoral vessels, reporting excellent delineation of vasculature in all 12 patients, even though tortuous and highly permeable arteries in glioblastoma multiforme traditionally challenge delineation by TOF. Furthermore, because gliomas tend to display greater angiogenesis with increasing grade, 7T TOF may be useful in noninvasive grading of gliomas. 7T TOF angiography may also prove useful in monitoring the success of antiangiogenic agents in slowing tumor growth.  

Brain Metastases. Early detection and delineation of brain metastases is critical in optimizing treatment planning. Historical strategies at conventional strengths, including higher dose contrast and magnetization transfer contrast imaging, have increased the detectability of enhancing metastases. Exploitation of susceptibility is another method to identify subtle lesions. Just as 3T demonstrates superior sensitivity for brain metastases compared with 1.5T, 7T MR imaging demonstrates 20% more cerebral microhemorrhages on SWI compared with 1.5T, even though the quantity of brain metastases on T1-weighted MP-RAGE is essentially equivalent. Because microscopic bleeding is common in brain metastases, 7T SWI may increase detection of very subtle metastatic disease. Direct comparison with 3T SWI is warranted. Increased susceptibility at higher field strengths may augment identification of metastatic brain foci over conventional techniques.  

Skull Base Tumors. The skull base is anatomically complex. High-resolution imaging can contribute greatly to preoperative planning. de Rotte et al were the first to demonstrate the feasibility of pituitary adenoma imaging at 7T; however, their study did not report on vascular sequences. Barrett et al used a semiquantitative rating system to demonstrate superior visualization of internal carotid artery branches and vasculature within skull base tumors using 7T TOF, despite higher B0 and B1 inhomogeneity artifacts at 7T. It does appear that TOF could benefit surgical navigation to minimize vascular injury during endoscopic pituitary surgery (Fig 1). Additional limitations associated with 7T skull base imaging include artifacts from proximity to large air-tissue interfaces, such as the sphenoid sinus. Future technical development including advanced shimming and parallel transmit will be important to overcome local magnetic field inhomogeneity.  

Most important, no study has directly compared noncontrast 7T TOF with contrast-enhanced 3T in the detection of intratumoral and adjacent vascular structures. Such an analysis is warranted because increased visibility of arterial structures at 7T may ultimately limit contrast administration for some patients.  

In their study of a homogeneous series of meningiomas at 7T, Song et al reported increased peri- and intratumoral vasculature and enhanced delineation of the tumor-brain interface in 4 patients with supratentorial meningiomas. Although the current diagnostic utility of conventional MR imaging for meningioma is already high, increased spatial resolution and SNR make 7T well-positioned to improve vascular characterization among these tumors.  

Treatment Monitoring for Tumors. Microhemorrhages are common sequelae following radiation therapy for intracranial neoplasms. Lupo et al reported high rates of microbleeds on 7T SWI among patients with glioma 2 years after radiation. Another study of 7T SWI in 113 patients having undergone focal radiation found a 100% incidence of at least 1 microbleed 2 years following radiation.  

Belleau et al further demonstrated the increased ability of 7T to detect radiation-related cerebral microbleeds using SWI, apparent transverse relaxation, and quantitative susceptibility mapping. Bian et al found significantly more cerebral microbleeds in 7T/10 patients with gliomas who underwent radiation therapy using 7T SWI compared with 3T SWI. However, when patients with 3 relatively inferior tumors were included, the effect between field strengths was not significant, suggesting that 7T SWI is more sensitive away from areas prone to inherent susceptibility artifacts. SWI at 7T, combined with tumor location consideration, may offer additional diagnostic value in early detection of radiation-induced microvascular damage.  

In addition to imaging vascular damage from radiation therapy, there is growing interest in leveraging 7T vascular imaging to monitor the efficacy of drug therapy for aggressive intracranial neoplasms. Grabner et al used 7T SWI to study longitudinal glioma microvasculature changes during antiangiogenic therapy, concluding that 7T SWI is useful for antiangiogenic therapy monitoring in patients with advanced disease. The feasibility of high-resolution imaging of intratumoral arteries has also been demonstrated with 7T TOF; however, its utility in assessing antiangiogenic efficacy has not yet been defined.
Dynamic contrast-enhanced imaging with 7T may also play an increasingly important role in the management of intracranial tumors and is a worthwhile area of technical development (Online Appendix and Online Fig 1).

**Epilepsy**

The benefits of 7T protocols for studying previously nonlesional epilepsy have recently been described. Vascular imaging sequences, in conjunction with structural MR imaging, hold promise in localizing cryptogenic seizure-onset zones in the setting of vascular lesions. It is estimated that up to 70% of symptomatic cavernomas cause seizures, approximately 40% of which are drug-resistant. Seizure freedom following cavernoma surgery is dependent on complete resection of the vascular malformation and metabolic products in the surrounding hemosiderin ring, and approximately 25% of patients with cavernoma-related epilepsy fail to achieve postoperative seizure freedom. The absence of an identifiable epileptogenic focus can disqualify certain patients from neurosurgery, necessitate invasive intracranial monitoring to localize seizure onset zone, and predispose patients who do progress to an operation to inferior postoperative outcomes. Advanced imaging tools may help clarify epileptogenesis and guide neurosurgical therapy.

Schlamann et al. found a greater number of cavernomas using T2*-weighted gradient-echo imaging at 7T compared with 1.5T, consistent with enhanced susceptibility that is known to occur at higher fields. This finding is supported by a prior study that reported increased cavernoma detectability at 3T compared with 1.5T SWI. In a series of 37 patients with epilepsy with various etiologies who had negative findings on MR imaging at a lower field strength, small cavernomas were identified in 3 patients, 2 of which were likely related to epileptogenesis. Developmental venous anomalies were detected in 4 other patients using 7T SWI, 2 of which coincided with regions of electrographic abnormality, suggesting possible occult cavernomas. In another study of 11 patients with epilepsy with negative findings on MR imaging, 1 patient’s diagnosis changed from suspected focal cortical dysplasia to cavernoma based on 7T SWI. Examples of 7T SWI for polymicrogyria and cavernoma as epileptogenic foci are shown in Fig 2 and Online Fig 2, respectively.

While these studies provide compelling evidence to support the use of 7T in vascular epilepsy imaging, no study has directly compared cavernoma detectability between 3T and 7T SWI. Comparison of Engel and quality-of-life scores between patients who underwent preoperative 7T versus conventional MR imaging may clarify the role of 7T imaging in treating cavernoma-related epilepsy. Although the importance of hemosiderin ring excision in cavernoma surgery is controversial, 7T MR imaging may facilitate a more precise definition of hemosiderin to optimize the resection of perilesional hemosiderin deposits.
Neurovascular Pathology

Aneurysm. Intracranial aneurysms occur in approximately 3% of the general population. Rupture and subarachnoid hemorrhage are associated with considerable morbidity and mortality. While neurosurgical treatment for intracranial aneurysms, including surgical clipping and endovascular coiling, are effective therapies, these procedures are not without risk. Therefore, identifying patients with aneurysms who are at high risk for rupture is critical in identifying appropriate candidates for preventative treatment. Advantages of 7T vessel wall imaging are increased SNR, higher spatial resolution, and greater CSF suppression compared with 3T. However, 7T imaging is limited by artifacts caused by increased transmit field ($B_1$) inhomogeneity. The superiority over lower-field MR imaging in vessel wall imaging remains inadequately understood.

Using gadolinium-enhanced MPRAGE 7T MR imaging, Sato et al reported 2 discrete aneurysm wall microstructures that are poorly resolved with lower-resolution MR imaging at lower field strengths: partial or complete enhancement of the inner wall (neovascularization) and outer wall (formation of the vasa vasorum). The latter pattern correlated histologically with vessel wall instability, suggesting that contrast-enhanced 7T MR imaging may be useful to characterize thrombosed intracranial aneurysms and could be a valuable clinical tool for determining rupture potential. Similarly, in comparing 1.5T and 7T TOF, Wrede et al reported that detectability and characterization of unruptured intracranial aneurysms were increased at 7T. In another study, 7T TOF provided delineation of unruptured intracranial aneurysms comparable with DSA, which is the current criterion standard. Such evidence suggests that 7T MR imaging may obviate ionizing radiation and iodinated contrast agent administration in the future. In a study of 21 saccular and 11 fusiform intracranial aneurysms using 0.4-mm isotropic 7T contrast-enhanced blackblood MR imaging, fusiform aneurysms exhibited superior wall enhancement due to increased resolution, image quality, and involvement of a larger surface than saccular aneurysms, reflecting differences in pathology.

Imaging hemodynamics and quantifying forces within vessels are another important component of predicting aneurysm rupture risk. Blankena et al used a TSE-based vessel wall sequence and phase-contrast 7T MR imaging to demonstrate an inverse relationship between vessel wall thickness and wall shear stress. Other advanced imaging techniques, including volume pulsation quantification, rotational angiography, and 4D flow, have been explored as aneurysm-rupture risk predictors at lower-field MR imaging; however, their implementation at 7T remains limited. As a result of artifacts, UHF quantification of volume pulsation of unruptured cerebral aneurysms is not currently possible, even with the high spatial resolution of 7T data. Additional applications of 7T TOF imaging have included differentiation between cerebral aneurysms and infundibula.

Despite these studies, it remains unclear whether 7T is more sensitive than lower-field MR imaging in detecting and characterizing cerebral aneurysms because there are relatively few direct comparison studies.

Atherosclerosis. Advanced high-resolution imaging methods may be useful in predicting atherosclerotic plaque rupture, embolization, and stroke (Fig 3). Harteveld et al, who used 3D gadolinium-enhanced T1-weighted 7T MR imaging to quantify atherosclerotic lesion burden in patients with posterior cerebral ischemia, confirmed greater lesion burden in the posterior cerebral artery. These results suggest that 7T contrast-enhanced vessel wall imaging may aid in the association between intracranial vessel wall lesions and ischemic events. Direct comparison of vessel wall imaging in an elderly asymptomatic population confirmed greater vessel wall visibility and more lesions at 7T compared with 3T. These authors suggested that the conspicuous of FIG 2. A patient with epilepsy with a subtle right-sided parieto-occipital polymicrogyria faintly seen on axial T2-weighted imaging at 3T (A, magnified inset B) with improved characterization at 7T (C, magnified inset D). Internal architecture and heterogeneity are also much better appreciated at 7T. SWI 7T minimum-intensity-projection demonstrates a cluster of venous structures (arrowheads) associated with the polymicrogyria (E, magnified inset F).
vessel wall lesions in the proximal anterior cerebral and posterior cerebral arteries is optimally imaged with 7T MR imaging.\(^{50}\) While 7T has been used to precisely measure circle of Willis vessel wall thickness in symptomatic and asymptomatic patients ex vivo,\(^{50}\) a direct comparison between symptomatic and asymptomatic patients in vivo is required for more definitive clinical utility.

A report on a cohort with mixed pathologies, including cerebral atherosclerotic lesions and aneurysms, compared vessel wall imaging with 3T and 7T T1-weighted sampling perfection with application-optimized contrasts by using different flip angle evolution (SPACE sequence; Siemens, Erlangen, Germany).\(^{51}\) MR imaging at 7T offered superior vessel wall characterization compared with 3T and greater visualization of the fibrous cap and lipid core among atherosclerotic plaques at 7T over 3T. Therefore, there may be a potential role of 7T MR imaging for diagnosis and risk stratification in intracranial vascular disease.\(^{51}\) By means of high-resolution 7T vessel wall imaging to determine the prevalence of vessel wall lesions, 96% of patients with vascular disease had at least 1 vessel wall lesion, nearly 3-fold the rate reported by the Atherosclerosis Risk in Communities Study at 3T.\(^{52,53}\) This discrepancy was attributed to differences in cohorts. Increased SNR at 7T MR imaging did contribute to higher detection of lesions. While these results suggest that 7T MR imaging may be useful in screening for intracranial vessel lesions and quantifying overall lesion burden, future studies are required to determine whether the smaller lesions detected only at UHF are clinically relevant.

Areas of wall thickening on imaging correspond to regions of advanced atherosclerosis with ex vivo 7T MR imaging.\(^{54}\) Additionally, 7T signal heterogeneity permitted spatial differentiation of constituent plaque components, including macrophages and collagen.\(^{54}\) Similar morphologic vessel wall properties at 3T and 7T, including vessel wall and luminal areas, were reported by others.\(^{55}\) However, 7T exhibited a significantly higher vessel wall SNR and contrast-to-noise ratio for both T1- and T2-weighted sequences.\(^{55}\) These results are similar to those of another carotid wall imaging study that reported significantly higher SNR at 7T compared with 3T, suggesting that 7T may be superior in diagnosing carotid vessel wall pathology.\(^{56}\) Majidi et al\(^{57}\) correlated in vitro intravascular sonography and 7T MR imaging findings with histology, concluding that 7T MR imaging is a reliable method of detecting burden within intracranial arteries.

**Stroke.** MR imaging at 7T has been used to characterize infarct morphology.\(^{58}\) When similar stroke protocols at 3T and 7T in patients with subacute and chronic stroke were compared, higher spatial resolution at 7T revealed more subtle features of ischemic lesions and infarct morphology compared with lower-field MR imaging.
imaging. Prior studies have successfully used 7T MR imaging to image occlusive changes in lenticulostriate arteries in acute and chronic stroke. Lenticulostriate arteries are difficult to image with conventional modalities due to their small size, but advances in 7T imaging have permitted excellent visualization at improved resolution with both T2-weighted and TOF imaging (On-line Fig 3). However, a direct comparison between 7T and lower field strengths for visualization of lenticulostriate artery features such as occlusion has not yet been quantified.

Moyamoya Vasculopathy. MR imaging at 7T has been applied to Moyamoya vasculopathy. Because revascularization surgery is a common treatment, high-resolution arterial imaging by DSA or CT angiography is used to plan surgery. However, 7T imaging may obviate contrast and radiation techniques. If one compared DSA, 3T MRA, and 7T MRA, all 3 were of diagnostic value, but 7T TOF was superior to 3T for detecting disease-specific small-vessel pathology. Furthermore, 7T and DSA provided similar results, despite motion artifacts being observed at 7T. While there were no significant differences between ICA diameters or ivy sign scores between field strengths, 7T exhibited higher sensitivity and specificity than 3T for detecting flow voids and provided superior depiction of slow-flowing blood within peripheral arteries. These preliminary studies using 7T MR imaging in characterizing abnormal vascular networks among patients with Moyamoya disease are promising and warrant further investigation.

Trigeminal Neuralgia. Trigeminal neuralgia is another pathology in which 7T MR imaging may find use. Vascular compression of the trigeminal nerve is the most common etiology; TOF plays an important role in diagnosing neurovascular conflict. TOF at 7T facilitates increased visualization of first- and second-order arterial branches that are poorly depicted at 1.5T or 3T. While trigeminal neuralgia can present without vascular compression, some cases of MR imaging negative for trigeminal neuralgia may result from offending vessels that are too small to see by conventional imaging methods. Therefore, 7T TOF may be particularly useful for patients with trigeminal neuralgia in whom lower-field scanning fails to confirm vascular compression. Although studies have applied 7T MR imaging to trigeminal imaging, no 7T study has coupled high-resolution TOF with structural or diffusion MR imaging to characterize neurovascular compression. Fusion of structural and high-resolution TOF imaging in trigeminal neuralgia is possible (Fig 4). Therefore, studies applying these techniques in patients with trigeminal neuralgia with nondiagnostic clinical MR imaging may clarify the value of 7T TOF in the diagnosis of neuropathic pain.

CONCLUSIONS

We described the emerging roles of vascular 7T MR imaging in neurosurgery and discussed current limitations of UHF neuroimaging. There has been considerable effort to apply vascular 7T MR imaging to conditions such as gliomas and vessel wall imaging, yet many unexplored applications of vascular imaging remain. The superior resolution and SNR of 7T compared with lower-field MR imaging in certain brain regions, coupled with technical developments that minimize susceptibility artifacts, are expected to expand the increasingly important role of 7T in the work-up of various neurosurgical diseases.
