Abstract—Digital data transfer can be protected by means of suitable error correcting codes. Among the families of state-of-the-art codes, LDPC (Low Density Parity-Check) codes have received a great deal of attention recently, because of their performance and flexibility of operation, in wireless and mobile radio channels, as well as in cable transmission systems. In this paper, we present a class of rate-adaptive LDPC codes, obtained as properly punctured simplex codes. These codes allow for the use of an efficient soft-decision decoding algorithm, provided that a condition called row-column constraint is satisfied. This condition is tested on small-length codes, and then extended to medium-length codes. The puncturing operations we apply do not influence the satisfaction of the row-column constraint, assuring that a wide range of code rates can be obtained. We can reach code rates remarkably higher than those obtainable by the original simplex code, and the price in terms of minimum distance turns out to be relatively small, leading to interesting trade-offs in the resulting asymptotic coding gain.

Index Terms—Golomb rulers, LDPC codes, Minimum Distance, Simplex codes

I. INTRODUCTION

Simplex codes are duals of Hamming codes [1]. In polynomial representation, for a binary finite field, they exhibit a parity-check matrix $H$ where a primitive binary polynomial $h(x)$ shifts along a diagonal trace, from left to right, by one position each row. On the cyclic code length $N$, the tern describing simplex codes is $[N,k,d]$, where $N = 2^k - 1$ is the block length and $d_{\min} = 2^{k - 1}$ is the code minimum distance. All the $2^k - 1$ non-null codewords have weight $d_{\min}$ [2]. Precisely, such non-null code words represent all the possible cyclic shifts of the same maximum-length pseudo-random binary sequence [3]. The parity-check polynomial $h(x)$ has degree $k$, with coefficients $h_0 = h_k = 1$, and can be interpreted as the generator polynomial of a Hamming code (the dual of our code) having the same cyclic code length $N$. In Fig. 1 the general form of such an $H$ matrix is shown. It exhibits $N$ columns and $N - k$ rows.

It is possible to choose a shorter code length $n$, with $n < N$, by eliminating external rows and hence external columns. This operation is called puncturing [4] and can be repeated as many times as one wishes. So $n$ becomes a variable, whereas $k$ does not change. After $s$ elementary row-column eliminations, the punctured code is described by the new tern $[n,k,d']$, with $n = N - s$, and the number of rows in the new parity-check matrix $H'$ is reduced to $r = n - k$. Finally, $d'$ is the new minimum distance. After this construction, the rows of the parity-check matrix remain all linearly independent, so that $H'$ still has full rank.

The code rate $\frac{k}{n}$ can be easily synthesized, leading to a rate-adaptive coding system. It is unavoidable that the new minimum distance $d'$ becomes smaller and smaller, for increasing values of $s$. Nevertheless, the main drawback of simplex codes, on their cyclic length $N$, that is a very low code rate, can be partially overcome. The problem of predicting word weight distributions and new minimum distances $d'$ for punctured binary simplex codes has already faced [5], [6]. Nevertheless, a research question remains open, regarding an efficient low-complexity soft-decision decoding procedure, able to exploit the good design characteristics of these codes. The main contribution of the present paper is in the interpretation of the parity-check matrix of simplex codes as a sparse matrix. Owing to this, the decoding algorithms which are suitable for Low-Density Parity-Check (LDPC) codes, can be adopted. In this context, the conditions for satisfying row-column constraint [7] will be investigated, in order to assure a straightforward decoding procedure, e.g. by means of the sum-product algorithm [8]. The availability of primitive polynomials to be chosen as $h(x)$ will be verified. Furthermore, a circulant expansion procedure [7] in designing the final form of the $H$ matrix will be suggested. Some simulations of the code performance on an Additive White Gaussian Noise (AWGN) channel will demonstrate feasibility of the proposed solution. The arguments are organized as follows. In Section II we provide some preliminary considerations. In Section III we obtain some theoretical results. In Section IV some word weight distributions are calculated, allowing to predict the progressive performance improvement for increasing values of

Fig. 1. General form of the parity-check matrix of (punctured) simplex codes. Out of the main diagonal band, only 0 symbols are present. Effects of $s = 2$ row-column eliminations, starting from the bottom right.
coefficients of the polynomial. Finally, we define the vector of length $n$

In other words, if there exist two pairs $\{i_1, j_2\}$ and $\{j_3, j_4\}$ such that $p_{j_2} - p_{j_1} = p_{j_3} - p_{j_4}$, also implying that $h_{j_1} = h_{j_2} = h_{j_3} = h_{j_4} = 1$. This is the condition of existence of a 4-length cycle, which corresponds to the dissatisfaction of the row-column constraint.

Now we will consider the properties emerging from an inspection of all the binary primitive polynomials for $k \in \{3, \ldots, 8\}$. Since they are formed by couples of reciprocal asymmetric polynomials [2], in Table I we report only one element for each couple. The notation adopted consists of representing the binary expressions of any polynomial. The number of different polynomials, on average, grows with $k$, but in this very small sample it is possible to recognize various typical well-known properties.

The weight $w$ of primitive polynomials is always an odd integer number, not smaller then 3. For many values of $k$, primitive polynomials with weight $w = 3$ are present. This is not true in few cases, say for $k = 8$, where the minimum weight is 5. Nevertheless 5-weight primitive polynomials, as what is known for $k$ up to 10,000, are always present when 3-weight polynomials are not [9]. We are interested in fixing conditions able to assure that the row-column constraint is satisfied.

III. ANALYSIS OF THE PROPERTIES OF PUNCTURED SIMPLEX CODES

In this section we study the properties of the considered codes, first focusing on parity-check polynomials with weight 3, and then generalizing the obtained results.

A. Codes characterized by parity-check polynomials of weight 3

Although the case of a 3-weight primitive polynomial gives only poor performance, we will investigate this case in detail, with the purpose of understanding the mechanisms of possible low-weight code word existence. The following property holds.

Theorem 2 Given a primitive polynomial of weight $w = 3$, the row-column constraint is always satisfied on a punctured simplex code.

Proof: The proof easily follows from the fact that primitive polynomials are always asymmetrical and are characterized by $h_0 = h_k = 1$. Given this, we have

$$p = [0, s_0, k],$$

where $s_0 \neq \frac{k}{2}$ because of the asymmetry. Then, $p$ is a Golomb ruler characterized by differences $s_0, s_1 = k - s_0$ and $k$, and the parity-check matrix constructed with $h(x)$ satisfies the row-column constraint, because of Theorem 1.
We can observe how the only degree of freedom in the design of a $k$-degree $3$-weight polynomial is in the choice of the central non-null power coefficient. Many properties characterizing punctured simplex codes of rate $\frac{1}{2}$ are independent of this choice.

**Lemma 1** In a $\frac{1}{2}$-rate punctured simplex code characterized by a $3$-weight parity-check polynomial, among the $2k$ columns of the resulting $H$ matrix, $k$ have weight $1$ and $k$ have weight $2$.

**Proof:** Using the symbolism in the proof of Theorem 2, we have the situation depicted in Fig. 2, where the diagonal solid lines in the matrix represent symbols $1$. Then, we note that the leftmost $s_0$ columns have weight $1$ (and support $0, 1, \ldots, s_0 - 1$, respectively) the central $k$ columns have weight $2$, and the rightmost $s_1$ columns have weight $1$ and support ($s_0 = k - s_1, \ldots, k - 1$, respectively). Being $s_0 + s_1 = k$, we have proved the thesis.

![Fig. 2. Structure of the parity-check matrix for code rate $\frac{1}{2}$ and a $3$-weight parity check polynomial](image)

Notice that the supports of the $1$-weight columns cover the whole set $\{0, 1, \ldots, k - 1\}$ without repetitions. This consideration leads to the following result.

**Theorem 3** Any $\frac{1}{2}$-rate punctured simplex code, constructed from a $3$-weight parity-check polynomial exhibits minimum distance $d_{\min} = 3$.

**Proof:** We have proven in Theorem 2 that $\frac{1}{2}$-rate punctured simplex codes constructed from a $3$-weight parity-check polynomial respect the row-column constraint. In other words, there are no $4$-length cycles in the parity-check matrix. Moreover, by construction, all the columns of weight $1$ have a different support. This implies that there cannot exist a pair of columns summing up (modulo $2$) to $0$. Therefore, $d_{\min} > 2$. Moreover, given any $2$-weight column in the central portion of $H$, with support $\{j_1, j_2\}$, by construction (see proof of Lemma 1) there exist a $1$-weight column on the leftmost portion of $H$ with support $j_1$ and a $1$-weight column on the rightmost portion of $H$ with support $j_2$. Then, these three columns sum up to zero modulo $2$, implying that $d_{\min} \leq 3$. So, we have $d_{\min} = 3$.

**Corollary 1** In the word weight distribution $A(\omega)$ of a $\frac{1}{2}$-rate punctured simplex code, constructed from a $3$-weight parity-check polynomial, $A(3) = k$ for $k > 3$, independent of the choice of $s_0$.

**Proof:** Codewords of weight $3$ in $\frac{1}{2}$-rate punctured simplex codes constructed from a $3$-weight parity-check polynomial can only have support given by the indexes of

1) three columns of $H$ of weight $1$, summing up to $0$ modulo $2$;
2) two columns of $H$ of weight $1$ and one of weight $2$, summing up to $0$ modulo $2$;
3) two columns of $H$ of weight $2$ and one of weight $1$, summing up to $0$ modulo $2$;
4) three columns of weight $2$ summing up to $0$ modulo $2$.

However, since all the columns of $H$ of weight $1$ have a different support, they cannot sum up to $0$ modulo $2$ and Case 1) is not possible. Case 3) is also impossible, since the sum modulo $2$ of two columns of weight $2$ has either weight $2$ or $4$, and therefore the sum modulo $2$ with a $1$-weight column cannot produce an all-zero vector. In order to study case 4), we notice that the $k$ central columns in Fig. 2 form a $2k$-length cycle. Since $k > 3$ by hypothesis, these columns do not contain $0$-length cycles, and therefore $3$-weight codewords. Therefore, also case 4) cannot occur. In case 2), we have $k$ columns of weight $2$ and for each of them there exists a pair of columns of weight $1$ such that these three columns sum up to $0$ modulo $2$, as shown in the proof of Theorem 3. Therefore, $A(3) = k$, independent of the value of $s_0$.

The case of a $\frac{1}{2}$-rate punctured simplex code, constructed from a $3$-weight parity-check polynomial for $k = 3$ is

| $k$ | $N$ | All the primitive polynomials, in binary representation |
|-----|-----|-----------------------------------------------------|
| 3   | 7   | 1101                                               |
| 4   | 15  | 11001                                              |
| 5   | 31  | 110001, 110111, 110111                             |
| 6   | 63  | 1100001, 1010111, 1110011, 1101101                  |
| 7   | 127 | 100011101, 100101101, 10110001, 10110101, 1101101 |
| 8   | 255 | 100111011, 100101011, 101100011, 101101011, 11111011, 11111011, 11111111 |
particular, since the 3 central columns form a 6-length cycle, and therefore \( A(3) = 4 \). This \([6, 3, 3]\) code turns out to be the well-known one-time punctured simplex code, which is selfdual and equivalent to the 1-time shortened Hamming code, with the same original length \( N = 7 \), whose overall weight distribution is \( A(0) = 1, A(3) = 4, A(4) = 3 \).

**B. Codes characterized by parity-check polynomials with higher weights**

Also 5-weight polynomials, and even 7-weight polynomials, if \( k \) is high enough, can exhibit all different separations (i.e., the associated \( p \) is a Golomb ruler) and hence satisfy the row-column constraint. For example, with \( k = 16 \), the coefficients of the 5-weight primitive polynomial are \( 100100000000010111 \). It is easy to check that the associated \( p = [0, 4, 13, 15, 16] \) is a Golomb ruler. In a similar way, with \( k = 121 \), the 7-weight primitive polynomial identified by the following exponents of non-null coefficients \( p = [0, 8, 25, 105, 115, 116, 121] \) is a Golomb ruler. Therefore, owing to Theorem 1, the row-column constraint is satisfied in both cases. Furthermore, qualitatively speaking, the absence of equalities requires the collection of a greater number of columns in the syndrome sum cancellation procedure for finding low-weight codewords, so intrinsically increasing the codeword weight.

In Fig. 3 the structure of the \( H \) matrix for code rate \( \frac{1}{2} \) and a 5-weight parity check polynomial is schematically shown. The differences between consecutive elements of \( p \) are named \( s_0, s_1, s_2, s_3 \) and \( s_0 + s_1 + s_2 + s_3 = k \). It is possible to draw the following extension of Lemma 2.

\[
\begin{align*}
\text{Fig. 3. Structure of the parity-check matrix for code rate } &\frac{1}{2} \text{ and a 5-weight parity check polynomial} \\
H &= \\
&\begin{bmatrix}
\text{s}_0 & \text{s}_1 & \text{s}_2 & \text{s}_3 & 1 \\
\text{s}_0 & \text{s}_1 & \text{s}_2 & 1 & 1 \\
\text{s}_0 & \text{s}_1 & 1 & 1 & 1 \\
\text{s}_0 & 1 & 1 & 1 & 1 \\
1 & 1 & 1 & 1 & 1
\end{bmatrix}
\end{align*}
\]

**Lemma 2** In an \( \frac{1}{2} \)-rate punctured simplex code characterized by a \( w \)-weight parity-check polynomial, among the \( 2k \) columns of the resulting \( H \) matrix, \( s_i + s_j \) have weight \( i + j - 1 \), where \( i \in \{0, \ldots, \frac{w-3}{2}\} \), \( j \in \{\frac{w-1}{2}, \ldots, w-2\} \) and \( i + j = w - 2 \).

**Proof:** Similar to the proof of Lemma 1.

The choice of the three central non-null powers in \( h(x) \) influences here the overall performance of the code. In spite of this consideration, the following property is verified about the average column weight \( < w_c > \) in the parity-check matrix, which represents an important parameter in order to evaluate decoding complexity.

**Theorem 4** In a punctured simplex code having parity-check polynomial weight \( w \), length \( n = \alpha k \), dimension \( k \), code rate \( R = \frac{k}{n} = \frac{k}{\alpha} \), the average column weight \( < w_c > = w(1 - R) \), independent of the vector of differences \( s \).

**Proof:** The thesis follows from the following equality

\[
< w_c > = (\alpha - 2) \frac{w}{n} + \sum_{i=0}^{w-2} s_i \frac{w}{n},
\]

due to the fact that \( (\alpha - 2)k \) columns have weight \( w \) and the remaining ones are as in a \( \frac{1}{2} \)-rate code. Then, by considering that \( k = \sum_{i=0}^{w-2} s_i \), we obtain

\[
< w_c > = (\alpha - 2)Rw + Rw,
\]

from which the thesis easily follows.

About the expected increase of the minimum distance \( d_{min} \), for a certain choice of \( w \) and vector of differences \( s \), as long as the code rate \( R \) is reduced with respect to \( \frac{1}{2} \), it can be justified by the following qualitative considerations, supported by a polynomial approach [10]. Owing to the properties of simplex codes, the cofactor \( g(x) \) of \( h(x) \) with respect to the binomial \( x^N + 1 \) is a long sequence of binary symbols, forming all the possible combinations of \( k \) elements except the one formed by \( k \) consecutive 0-symbols. Code rate reduction from \( \frac{1}{2} \) to \( \frac{1}{\alpha} \), with \( \alpha' = \alpha + 1 \), implies the addition to all the previous codewords of \( k \) consecutive symbols taken from the vector of coefficients of \( g(x) \). In such packet of additional \( k \) symbols there will be at least one 1-symbol, so leading to the increment of one unit in the previous minimum distance. Nevertheless, in the next section, some examples of much higher increments will be presented.

**IV. Word weight distributions**

As long as the weight of \( h(x) \) increases the performance in terms of minimum distance and word weight distribution \( A(w) \) progressively improve. In Table II, we show the weight distributions (for low weights) of three codes, all derived from the same 3-weight \( h = 10010001 \), which is characterized by \( k = 7 \), selecting different values of the block length \( n \), in order to have code rate \( R = \frac{7}{12}, \frac{7}{13}, \frac{7}{14} \). The minimum distance \( d_{min} \) grows from \( d_{min} = 3 \) to \( d_{min} = 5 \) and finally to \( d_{min} = 9 \). Also the asymptotic coding gain, for a soft-decision decoding, that is the parameter \( G(\infty) = R d_{min} \), has been calculated. All the possible polynomials with weight 3 show the same word weight distribution, up to \( A(5) \) at code rate \( \frac{2}{5} \). Some small differences appear at lower code rates.

With \( h(x) \) having weight 5, the particular choice of \( h(x) \) can induce remarkable behavior differences. In Table III we have considered a 5-weight primitive polynomial characterized by \( k = 16 \). Its binary representation is \( 1000100000000010111 \) and the associated \( p \) is a Golomb ruler. In this case, we obtain a minimum distance growing from \( d_{min} = 5 \) to \( d_{min} = 10 \) and...
finally to \(d_{\text{min}} = 16\). Correspondingly, \(G_{\infty}\) increases from 4 dB to 6 dB.

Considering that we are dealing with very small block lengths, the results obtained appear encouraging. In particular, the code identified by the tern \([64, 16, 16]\) is characterized by the same parameters as the direct product of a pair of extended Hamming codes \([8, 4, 4]\), but the coefficient \(A(16)\) is here much smaller.

In both the shown examples, the number of low-weight code words appears very small, yielding a relatively rapid reaching of the asymptotic coding gain \(G_{\infty}\). In Fig. 4 we show the Truncated Union Bound (TUB) on the Bit Error Rate (BER) as a function of the Signal-to-Noise Ratio (SNR), for the codes in Table III, computed as

\[
\text{BER}_{\text{TUB}} \approx \sum_{w=d_{\text{min}}}^{d^*} \frac{1}{2^n} \frac{A(w) \text{erfc} \left( \sqrt{\frac{k}{w-n}} \frac{E_b}{N_0} \right)}{n},
\]

where \(d_{\text{min}} \leq d^* \leq n\). Clearly, the larger \(d^*\), the tighter the TUB to the complete union bound (obtained for \(d^* = n\)). The considered values of \(d^*\) are 7, 12 and 18, respectively.

V. NUMERICAL SIMULATIONS

In this section we have simulated the performance of some punctured simplex codes of rate \(\frac{1}{4}\), by means of Monte Carlo simulations of Binary Phase Shift Keying (BPSK) transmissions over an Additive White Gaussian Noise (AWGN) channel. We have adopted a decoding algorithm of the belief propagation family, commonly used to decode LDPC codes. Namely, we have considered the sum-product decoding algorithm [8], performing 100 iterations. The complexity of this algorithm grows linearly with the (average) column weight of the input parity-check matrix (see [11, Section II]).

The first considered code, \(C_1\), is defined by a 7-weight parity-check polynomial, characterized by \(k = 121\), such that \(p = [0, 8, 25, 105, 115, 116, 121]\), which is a Golomb ruler and, therefore, \(C_1\) satisfies the row-column constraint.

The second considered code, \(C_2\), is defined by a 7-weight parity-check polynomial, characterized by \(k = 240\), such that \(p = [0, 25, 31, 138, 150, 160, 240]\), which is a Golomb ruler, too.

Finally, we have derived a third code, \(C_3\), from \(C_1\), by applying the so-called circulant expansion technique, which was first proposed in [12] (though on different matrices) and further investigated in [7]. In a nutshell, when using this technique, each 1-symbol of the starting parity-check matrix is substituted by a circulant permutation matrix of side \(p\), and each 0-symbol is substituted by an all-zero matrix of side \(p\). This is known to improve the error rate performance of the starting code (see [13] for a performance evaluation with increasing values of \(p\)). In this case, we have used matrices of side \(p = 7\). The \(i\)th 1-symbol in each row of the parity-check matrix of \(C_1\) has been substituted by a circulant permutation matrix, such that the support of its first column is \(i\), when \(i\) is odd, and \((2i \mod 7)\) when \(i\) is even. The resulting code

### Table II

| \(n\) | \(k\) | \(R\) | \(d_{\text{min}}\) | \(G_{\infty}\) | \(A(w)\) | \(< w_{\text{c}} >\) |
|------|------|------|----------------|-------------|-----------|----------|
| 14   | 7    | \(\frac{1}{4}\) | 3             | 1.8 dB      | \(A(4) = 7, A(4) = 7, A(5) = 7, A(6) = 21\) | 1.5      |
| 21   | 7    | \(\frac{1}{4}\) | 5             | 2.2 dB      | \(A(5) = 1, A(6) = 11, A(7) = 3, A(8) = 4\)   | 2        |
| 28   | 7    | \(\frac{1}{4}\) | 9             | 3.5 dB      | \(A(9) = 7, A(10) = 7, A(11) = 6, A(12) = 7\) | 2.25     |

### Table III

| \(n\) | \(k\) | \(R\) | \(d_{\text{min}}\) | \(G_{\infty}\) | \(A(w)\) | \(< w_{\text{c}} >\) |
|------|------|------|----------------|-------------|-----------|----------|
| 32   | 16   | \(\frac{1}{8}\) | 5             | 4 dB        | \(A(5) = 2, A(6) = 22, A(7) = 67\)            | 2.5      |
| 48   | 16   | \(\frac{1}{8}\) | 10            | 5.2 dB      | \(A(10) = 4, A(11) = 12, A(12) = 3\)           | 3.33     |
| 64   | 16   | \(\frac{1}{8}\) | 16            | 6 dB        | \(A(16) = 3, A(17) = 11, A(18) = 17\)          | 3.75     |
C₃ is quasi-cyclic and has dimension \( k = 121 \cdot 7 = 847 \). Its parity-check matrix does not contain 4-length cycles, since the circulant expansion technique preserves the satisfaction of the row-column constraint [14].

The performance of these codes in terms of BER is shown in Fig. 5. We notice that, with respect to the uncoded case, the proposed codes obtain a relatively large gain. Moreover, Fig. 5 confirms that punctured simplex codes can be efficiently decoded as LDPC codes, significantly reducing the decoding latency and complexity.

![Fig. 5. Bit error rate performance of codes C₁, C₂ and C₃, as a function of the SNR.](image)

We have also considered a fourth code, \( C₄ \), defined by a 7-weight parity-check polynomial, characterized by \( k = 75 \), such that \( p = [0, 2, 21, 29, 60, 72, 75] \), and compared it with two of the LDPC codes considered in [15], having \( k = 64 \): an accumulate-repeat-jagged-accumulate (ARJA) LDPC code and an accumulate-repeat-3-accumulate (AR3A) LDPC code. The results are shown in Fig. 6, where we notice that our newly designed code has comparable block length and error rate performance with codes widely employed in standards.

![Fig. 6. Codeword error rate performance of codes C₄ and two codes from [15], as a function of the SNR.](image)

VI. CONCLUSION

For any value of the cyclic length \( N = 2^k - 1 \) characterizing a binary simplex code, a family of rate adaptive LDPC codes can be found. This property follows from the existence of a \( w \)-weight parity-check primitive polynomial. If such a polynomial also corresponds to a Golomb ruler, the parity-check matrix of the code does not contain 4-length cycles, which are known to degrade the code performance in terms of error rate when belief propagation-based algorithm are used for decoding. If the parity-check polynomial is not associated to a Golomb ruler, the residual 4-length cycles can be eliminated by properly substituting each non-zero symbol associated to a Golomb ruler, the residual 4-length cycles can be eliminated by properly substituting each non-zero symbol.
