Resonantly excited precession motion of three-dimensional vortex core in magnetic nanospheres

Sang-Koog Kim\textsuperscript{1}, Myoung-Woo Yoo\textsuperscript{2}, Jehyun Lee\textsuperscript{1,†}, Ha-Youn Lee\textsuperscript{1}, Jae-Hyeok Lee\textsuperscript{1}, Yuri Gaididei\textsuperscript{2}, Volodymyr P. Kravchuk\textsuperscript{2} & Denis D. Sheka\textsuperscript{3}

We found resonantly excited precession motions of a three-dimensional vortex core in soft magnetic nanospheres and controllable precession frequency with the sphere diameter $2R$, as studied by micromagnetic numerical and analytical calculations. The precession angular frequency for an applied static field $H_{DC}$ is given as $\omega_{MV} = \gamma_{\text{eff}} H_{DC}$, where $\gamma_{\text{eff}} = \gamma \langle m_{\Gamma} \rangle$ is the effective gyromagnetic ratio in collective vortex dynamics, with the gyromagnetic ratio $\gamma$ and the average magnetization component $\langle m_{\Gamma} \rangle$ of the ground-state vortex in the core direction. Fitting to the micromagnetic simulation data for $\langle m_{\Gamma} \rangle$ yields a simple explicit form of $\langle m_{\Gamma} \rangle \approx (73.6 \pm 3.4) (l_{ex}/2R)^{2.20 \pm 0.14}$, where $l_{ex}$ is the exchange length of a given material. This dynamic behavior might serve as a foundation for potential bio-applications of size-specific resonant excitation of magnetic vortex-state nanoparticles, for example, magnetic particle resonance imaging.

The Larmor precession is a universal dynamic phenomenon in nature that represents the precession of a magnetic moment about a magnetic field at a characteristic Larmor frequency, which is expressed as $\omega_L = \gamma H$, where $\gamma$ is the gyromagnetic ratio and $H$, the static field strength. This type of precession plays very crucial roles in a rich variety of electron- or nuclei-spin-related dynamics such as electron-spin resonance, nuclear magnetic resonance, ferromagnetic resonance, and related magnetization dynamics.\textsuperscript{1–6} Such dynamic fundamentals have been widely utilized in a significant number of applications, including material analysis,\textsuperscript{4,7} bio-medical imaging,\textsuperscript{7,8} and information recording in magnetic media.\textsuperscript{9,10}

In this paper, we report the discovery of resonantly excited precession motions of a magnetic vortex core in soft magnetic nanoparticles of spherical shape,\textsuperscript{11} but with totally different underlying physics from those for vortex motions so far reported.\textsuperscript{12–17} We also were able to identify sphere-size-controllable precession angular frequency $\omega_{MV}$ and size-specific resonant excitations of nanoparticles bearing a magnetic vortex structure. We additionally determined, based on combined micromagnetic numerical and analytic calculations, that the size specificity of $\omega_{MV}$ originates from the variable effective gyromagnetic ratio with the sphere size that modifies the vortex structure inside spheres. Our results could provide a potential means of implementing size-specific resonant excitation of nanoparticles in bio-applications.\textsuperscript{18}

Results

Ground states of nanospheres. Figure 1a shows a nanosphere model of spherical symmetry. As described in Methods, we performed micromagnetic numerical calculations on Permalloy (Py, Ni_{80}Fe_{20}) nanoparticles of different diameters, 2R = 10 nm – 150 nm (see Methods). Figure 1b illustrates the ground states of the spheres obtained through relaxation from their saturated states in the +x direction. For the 2R < 40 nm cases, uniformly magnetized single-domain states were obtained, whereas for the 50 nm ≤ 2R ≤ 150 nm cases, single magnetic vortex states were well established. The vortex state of the 2R = 150 nm sphere, for example, was visualized by streamlines circulating around the vortex core oriented in the +x direction. We noted that the region of the vortex core aligned in the +x direction relative to the region of the in-plane circulating magnetizations varies markedly with 2R, as indicated by the x-component of the local magnetizations, m_x = M_x/M_s (see the color bar). The arrows inside the sphere of 2R = 150 nm represent the local curling magnetizations. (c) m_x profiles along y axis for different diameters. The inset shows the m_x profiles versus the normalized distance for each diameter.

Figure 1. Ground-state magnetization configurations of Py nanospheres according to the diameter. (a) Finite-element sphere model for diameter 2R = 30 nm. (b) Ground-state magnetization configurations of Py nanospheres for different 2R values as indicated: upper, viewed from positive z-direction and sliced across x-y plane; lower, viewed from positive x-direction and sliced across y-z plane. The color represents the x-component of the local magnetizations, m_x = M_x/M_s (see the color bar). The arrows inside the sphere of 2R = 150 nm represent the local curling magnetizations. (c) m_x profiles along y axis for different diameters. The inset shows the m_x profiles versus the normalized distance for each diameter.

Resonantly excited precession motion of a vortex core in spheres. Since the spherical symmetry of nanospheres does not lead to any magnetic shape anisotropy, when a sizable static field H_{DC} is applied in the +z direction, the vortex cores for 40 nm < 2R ≤ 150 nm start to reorient to the field direction, but with accompanying precession motions (see Supplementary Movie). This precession motion is different from the well-known gyration and even its higher-order modes of vortex cores in planar dots^{12–17}. Although very weak spin waves are emitted inside the nanospheres, the vortex’s spin configurations are maintained as a whole structure, because the field strength is sufficiently small. In the relaxation process, the core orientation converges in the field direction (+z-direction), reflecting the fact that the m_x averaged over the entire volume of the sphere,  \langle m_x \rangle, undergoes decaying oscillation through its vortex-core precession (inset of Fig. 2a). The precession frequency was obtained by Fast Fourier Transformation (FFT) of the temporal  \langle m_x \rangle  evolution for the different values of 2R and H_{DC} (see Fig. 2a,b, respectively). In the cases of uniformly saturated particles (2R = 10, 20, or 30 nm), the
frequency was independent of $2R$, as determined by the Larmor frequency $f_L = (\gamma/2\pi)H_{DC}$\(^{19}\). By contrast, for the vortex-state spheres ($40 \text{ nm} \leq 2R \leq 120 \text{ nm}$), the precession frequency of a vortex core showed a strong variation with $2R$, as can be expressed by $f_{MV} = (\gamma_{\text{eff}}/2\pi)H_{DC}$, where $\gamma_{\text{eff}}$ is the effective gyromagnetic ratio, which is variable with the sphere diameter.

In order to quantitatively elucidate the $\gamma_{\text{eff}}$-versus-$2R$ relation, we plotted the value of $f/H_{DC}$ as a function of $2R$, both of which were obtained from the micromagnetic simulations. As shown in Fig. 3, when $\gamma/2\pi = 2.8$ (MHz/Oe) on the left axis is scaled to $\langle m_{\Gamma} \rangle = 1$ on the right axis, both numerical values are in excellent agreement over the entire range of diameters studied, resulting in an explicit form of $\gamma_{\text{eff}}/\gamma = \langle m_{\Gamma} \rangle$ (for single-domain states, $\gamma_{\text{eff}} = \gamma$, because of $\langle m_{\Gamma} \rangle = 1$). Therefore, the precession frequency of a vortex core in nanospheres can be expressed as $f_{MV} = (\gamma/2\pi)\langle m_{\Gamma} \rangle H_{DC}$. This precession frequency cannot be explained by the gyration mode (or even by higher-order modes) of vortex cores in thin or thick film dots, and neither, consequently, by Thiele’s equation\(^{12–17}\).

**Analytical derivation of vortex-core precession in nanospheres.** In order to gain physical insight into the $f_{MV} = (\gamma/2\pi)\langle m_{\Gamma} \rangle H_{DC}$ relation obtained from the micromagnetic simulations, we analytically derived vortex-core precession dynamics in nanospheres. In our modeling, a weak static field was applied in the $+z$ direction, which field sustained the rigid vortex structure in a certain potential, and thus allowed the initial ground-state vortex core to align in the $+z$ direction through the precession around the field direction along with certain damping. We used the local spherical reference frame on infinitesimal segments of the surface, where the unit vector of local magnetizations is expressed as $\vec{m} = (m_r, m_\theta, m_\phi)$, $r$ is the radial distance, $\theta$ is the polar angle, and $\phi$ is the azimuthal angle, as shown in Fig. 4a. Time-variable vortex-core orientation can be defined as a unit vector $\vec{\Theta} = \arctan\left(\frac{\sin\theta \cos\phi}{\sin\theta_0 \sin\gamma_0}, \frac{\sin\phi_0}{\cos\gamma_0}\right)$, as illustrated in Fig. 4b. Following the rigid vortex Ansatz, which agreed with the micromagnetic simulation results, local magnetizations inside a given sphere could be expressed as $m_r = f(r, \Gamma \cdot \hat{r})$ and $\Phi = -\arctan\left(\frac{\Gamma \cdot \hat{r}}{\Gamma \cdot \hat{\phi}}\right)$, where $\Phi$ is the azimuthal angle of the magnetization in the local spherical reference frame (inset of Fig. 4a). Here we assume some general shapes of $m_r$ that are restricted by the condition $f(r,1) = -f(r,-1) = 1$ for all $r$ values. Since $m_r,$
and Φ are canonically conjugated variables, the time evolution of the local magnetizations can be determined from the Landau-Lifshitz-Gilbert (LLG) equations

\[
\dot{m}_r = -\frac{\gamma}{M_s} \frac{\delta E}{\delta \Phi} - \alpha (1 - m_r^2) \dot{\Phi},
\]

(1a)

Figure 3. Precession frequency normalized by \(H_{DC}\) (circles) and \(\langle m_T \rangle\) (crosses) obtained from micromagnetic numerical calculations. The value of \(\gamma/2\pi = 2.8\) (MHz/Oe) on the left axis is scaled to \(\langle m_T \rangle = 1\) on the right axis. The different colors of the circle symbols indicate the numerical data for different sphere diameters, as indicated by the colors shown in Fig. 2a. The solid curve is the result of a numerical calculation of the analytical form of \(\langle m_T \rangle \approx (73.6 \pm 3.4) (l_c/2R)^{2.20 \pm 0.14}\).

Figure 4. Model for analytical derivations. (a) Definition of spherical coordinates and local spherical reference frame (colored surface) for local magnetization \(m\). (b) Schematic of model sphere wherein single rigid vortex core is pointed in direction of \(\theta_0\) and \(\phi_0\), as defined by the polar and azimuthal angle coordinates.
\[ \dot{\Phi} = \frac{\gamma}{M_s} \frac{\delta E}{\delta m_r} + \frac{\alpha}{1 - m_r^2} m_r. \] (1b)

By inserting the \( m_r \) distribution function of the vortex’s spin configuration into Eqs. (1a) and (1b), we finally obtained the governing equation for vortex-core precession motion,

\[ \dot{\Gamma} + \frac{\gamma}{M_s V} \Gamma \times \frac{\partial E}{\partial \Gamma} + \frac{\alpha}{V} \Gamma \times \frac{\partial F}{\partial \Gamma} = 0 \] (2)

where \( E \) is the total magnetic energy, \( F \) is a dissipative functional \( \left\{ F = \frac{V}{2} \int d\mathbf{r} \left[ \sin^2 \Theta \left( \frac{\partial \Phi}{\partial \mathbf{r}} \cdot \hat{\mathbf{r}} \right)^2 + \left( \frac{\partial \Phi}{\partial \mathbf{r}} \times \hat{\mathbf{r}} \right)^2 \right] \right\} \), and \( V = \frac{4}{3} \pi R^3 \) is the sphere volume. The first, second and third terms in Eq. (2) correspond to the gyrotrropic, potential energy and damping terms, respectively. The total energy \( E \) under a weak magnetic field applied along the \( z \)-axis, \( \mathbf{H} = H_{DC} \hat{z} \), can be expressed simply as \( E_{\text{TH}} = -\hat{z} \cdot \Gamma(t) H_{DC} V M_s \langle m_r \rangle \), where \( \langle m_r \rangle \) is rewritten as \( \langle m_r \rangle = \frac{1}{M_s V} \int d\mathbf{r} \langle \mathbf{M} \cdot \hat{\mathbf{r}} \rangle \). Eq. (2) expresses the precession motion of vortex cores in collective spin dynamics; it differs from Thiele’s equation to describe the gyration of vortex cores in planar dot systems.

By inserting \( E_{\text{TH}} \) into Eq. (2) and assuming negligible damping, the precession frequency of a rigid vortex core can be given as \( \Phi = 2 \pi f_{\text{TH}} \) with \( f_{\text{TH}} = \langle \gamma(2\pi) \rangle \langle m_r \rangle H_{\text{DC}} \). Consequently, we obtained the effective gyro magnetic ratio of the motion of a vortex in a given nanosphere as \( \gamma_{\text{eff}} = \gamma \langle m_r \rangle \). This analytic form provides a clear physical insight into 2R-dependent \( f_{\text{TH}} \), because \( \langle m_r \rangle \), as indicated in the micromagnetic simulation results, varies with \( 2R \). Here we note that the eigenfrequency of a single vortex in cylindrical dots is known to vary with the aspect ratio of thickness \( L \) to \( R \), however, the \( \langle m_r \rangle \)-dependent \( \gamma_{\text{eff}} \) versus \( 2R \) curve for a given value of \( 2R = 50 \) nm and a given material \( \gamma_{\text{eff}} \) varies with \( 2R \) in the \( 50–200 \) nm range for the material of \( \gamma_{\text{eff}} \) is related to the competition between the short-range, strong exchange interaction and long-range, but relatively weak dipolar interaction in nanospheres of given dimensions.

Dependence of \( \langle m_r \rangle \) on sphere’s diameter and constituent material parameters. Next, it is necessary to quantify how \( \langle m_r \rangle \) varies with \( 2R \). We estimated, from further micromagnetic numerical calculations, the quantitative relation between \( \langle m_r \rangle \) and \( 2R \) within the \( 2R = 50–200 \) nm range for the different material parameters of both \( M_s \) and \( A_{\text{ex}} \). Figure 5 reveals that \( \langle m_r \rangle \) is given as \( \langle m_r \rangle \approx \eta \left[ A_{\text{ex}} / (2 \pi M_s^2) \right]^{1.09 \pm 0.05} \left( 2R \right)^{-2.21 \pm 0.13} \) with \( \eta = 73.6 \pm 3.4 \). According to the relation \( l_{\text{ex}} = \sqrt{A_{\text{ex}} / (2 \pi M_s^2)} \), \( \langle m_r \rangle \) can be simplified as \( \langle m_r \rangle \approx \eta \left( 73.6 \pm 3.4 \right) l_{\text{ex}} / 2R \) with \( l_{\text{ex}} \). For example, the critical diameter, \( 2R = 37.3 \) nm for Py, was in good agreement with that obtained from the simulation results shown in Fig. 1. As quantitatively interpreted, the strong variation of \( \langle m_r \rangle \) versus \( 2R \) for a given material is related to the competition between the short-range, strong exchange interaction and long-range, but relatively weak dipolar interaction in nanospheres of given dimensions.

Size-specific resonant excitations. As an application of the aforementioned fundamental dynamics, we could activate magnetic nanoparticles of a specific size by tuning the frequency of an applied AC field to the \( f_{\text{MV}} \) of a sphere of a given diameter and material. In this modeling, an external AC field and a static field were given by \( \mathbf{H}_{\text{AC}} = H_{\text{AC}} \sin(2 \pi f_{\text{AC}} t) \hat{y} \) and \( \mathbf{H}_{\text{DC}} = H_{\text{DC}} \hat{z} \), respectively, with sufficiently small values of \( H_{\text{AC}} = 10 \) Oe and \( H_{\text{DC}} = 100 \) Oe to avoid deformation of the initial vortex structures in the Py spheres. Figure 6a shows the oscillation of the core orientation \( \theta_0 \) from the \( +z \) direction during the precession process for \( 2R = 60 \) nm (\( f_{\text{MV}} = 95 \) MHz), as excited by \( f_{\text{AC}} = 91, 95 \) and \( 99 \) MHz. The oscillation of \( \theta_0 \) was hardly observable for the cases where \( f_{\text{AC}} \) was far from \( f_{\text{MV}} \) whereas it was very large for the case of \( f_{\text{AC}} = f_{\text{MV}} \), that is, at resonance. The resonantly excited precession leads even to vortex-core reversals between \( \theta_0 = +\pi \) and \( 0 \), as such reversals in planar disks occur periodically by linearly oscillating fields or currents applied on the disks’ plane under the resonance condition \( 22,23 \). The oscillation of \( \theta_0 \) represents a transfer of the external magnetic field to a magnetic sphere via the absorption of the Zeeman energy and subsequent emission to another form. The maximum energy absorption can be defined by the first maximum energy increment, \( \Delta E_{\text{TH}} \), as noted in Fig. 6a. Figure 6b plots \( \Delta E_{\text{TH}} \) versus \( f_{\text{AC}} \) for different sphere diameters \( 24 \). For each diameter, the maximum peak height \( \Delta E_{\text{max}} \) in the \( \Delta E_{\text{TH}} \)-versus-\( f_{\text{AC}} \) curves was obtained under the corresponding resonance condition. All of the curves were well separated from each other, indicating reliable size-specific excitation of the magnetic particles. For example, the difference in \( f_{\text{MV}} \) between the 50 and 60 nm particles was about 50 MHz, which is sufficiently large compared with the full width at half maximums of both particles, 6.6 and 9.9 MHz, respectively.

In Fig. 6c are shown the \( \Delta E_{\text{max}} \)-versus-\( 2R \) curves for comparison between the simulation data (solid circles) and the analytical form (lines) of the Zeeman energy, \( \Delta E_{\text{max}} = 2H_{\text{DC}} V M_s \langle m_r \rangle \), where \( \langle m_r \rangle = 1 \).
for single-domain states or \( \langle m_y \rangle \approx (73.6 \pm 3.4)(l_x/2R)^{1.24 \pm 0.14} \) for vortex states. The simulation and analytical calculation agreed very well, as can be seen. The analytical calculation clearly shows that the magnetic energy absorption varies with \((2R)^3\) and \((2R)^{0.8}\) for the single-domain and vortex states, respectively. These results suggest that the magnetic energy absorption can be maximized by tuning \( f_{AC} \) to the resonance frequency of a given-diameter particle. This effect is made possible through size-specific resonance, size-selective activation and corresponding detection of the magnetic nanoparticles of a vortex state.

Discussion

We discovered, by micromagnetic numerical calculations, not only the resonantly excited precession motion of a vortex core in nanospheres and its size-dependent precession frequency, but also its physical origin, based on the size effect on the effective gyromagnetic ratio in collective spin dynamics analytically derived. This finding paves the way for size-selective activation and/or possible detection of magnetic nanoparticles by application of extremely low-strength AC fields tuned to the resonant frequency of a given diameter and material. These results, notably, would be applicable to magnetic particle resonance imaging (MPRI) and bio-applications.

Methods

In our micromagnetic numerical calculations, the FEMME code (version 5.0.8)\(^{25}\) was used to numerically calculate the motions of the magnetizations of individual nodes (mesh size: \( \leq 4 \text{ nm} \)) interacting with each other via exchange and dipolar interactions at the zero temperature, as based on the LLG equation\(^{20,21}\). The surfaces of the model spheres were discretized into triangles of roughly equal area.

\[ A_{ex}/A_{ex,py} = 1 \]

\[ M_s/M_{s,py} = 0.6 \]

\[ A_{ex}/A_{ex,py} = 1.4 \]

\[ M_s/M_{s,py} = 0.6 \]

\[ A_{ex}/A_{ex,py} = 1.4 \]

\[ M_s/M_{s,py} = 0.6 \]

\[ 2R = 100 \text{ nm} \]
using Hierarchical Triangular Mesh (HTM), as shown in Fig. 1a, in order to prevent irregularity-incurred numerical errors26. The chosen material parameters corresponding to Py were as follows: saturation magnetization $M_s = 860$ emu/cm$^3$, exchange stiffness $A_{ex} = 1.3 \times 10^{-6}$ erg/cm, damping constant $\alpha = 0.01$, $\gamma/2\pi = 2.8$ MHz/Oe, and zero magnetocrystalline anisotropy for the soft ferromagnetic Py material.
