Keywords: cadmium; heavy metal toxicity; immune privilege; male fertility; testis transplantation; T regulatory cells.

Introduction

Cadmium (Cd) is a widespread and non-biodegradable pollutant of great concern to human health. This element can affect cellular signal transduction and cell-to-cell interaction in the testis. Immune tolerance towards auto- and alloantigens is an important component of testis immunity. It is involved in spermatogenesis and hormone secretion. Plus, the immune tolerance may help to reveal the changes in testis immunity over a long period after Cd exposure. The current research was aimed at investigating the long-term effects of acute Cd exposure on testis immunity by means of elicitation of testicular immune cell composition shift induced by Cd.

Cadmium chloride was intraperitoneally injected at 3 mg Cd/kg to mice. After that testis interstitial cells were stained with surface markers for leukocyte and lymphocyte subpopulations (CD45, CD11b, CD3, CD4, CD8, CD25) and analyzed cytofluorimetrically by week 4, 8, 12 and 16 after Cd administration (Cd group). To identify the delayed effects of cadmium on immune tolerance two groups of animals were subjected to intratesticular allotransplantation of neonatal testis (groups ITT and Cd ITT). One of the groups was administered with Cd four weeks before the transplantation (Cd ITT group). I group served as a control that did not undergo any transplantation or Cd injection. For a better demonstration of the phenomenon of immunological tolerance of the testicles, an additional group (UKT group) was used which got grafts under the kidney capsule (non-immune privileged site).

The change in testis immunity over a long period after Cd exposure might induce irreversible injuries in multiple organs such as liver, kidney, brain, lungs and testes (Yang & Shu, 2015; Hu et al., 2017; Halder et al., 2019). The testis is known for its immune privilege status. This evolutionary adaptation protects spermatogenesis from the autoimmune system. Testicular immune privilege is a complex phenomenon which is a result of the combined contribution of cellular and humoral components of testes rather than a single cell type or humoral factor acting alone. Few attempts were undertaken to assess the change in the testicular immune component and immune privilege status after Cd pretreatment. It has been shown that Cd injection resulted in an increase in the...
level of pro-inflammatory cytokine (TNF-α) and in the alteration of macrophage shape and composition compromising immune privilege (Chakraborty et al., 2014). However, the abovementioned changes were investigated immediately after Cd exposure.

Hence, it is interesting to investigate the consequences of Cd exposure on a long-time scale after Cd administration and the profile of some testicular immune cells playing a role in the testis immunity such as macrophages, dendritic cells, T lymphocytes. Intratesticular testis transplantation may provide a model for the investigation of testicular defects (Schlatt et al., 2003; Hutka et al., 2017). One consequence of the immune privilege is the ability to prolong the survival of intratesticular transplanted graft. Thus, this feature can potentially be used for the assessment of the long-term changes in testicular immune privilege status after Cd exposure when Sertoli and germinal cell contact were compromised long before the transplantation. Additionally, the investigation of testicular tissue under transplantation itself may contribute to the development of new approaches for breeding laboratory animals (Shaw & Trounson, 2002; Schlatt et al., 2003) and human reproductive technology (McCracken & Nahata, 2017).

Therefore, this study aims to understand the inter-relation between testicular immune cells such as macrophage, granulocytes and some types of lymphocytes in maintaining normal immune status in the testis and the mechanism by which Cd disrupts this harmony at the cellular level. The results may provide an insight into the long-term impact of Cd on an organism in order to develop novel treatment approaches for acute and chronic Cd intoxication and for male fertility preservation or restoration.

Materials and methods

Male CBA mice were kept in the animal house of the Institute for Problems of Cryobiology and Cryomedicine of the National Academy of Sciences of Ukraine (Kharkiv, Ukraine). The animals were housed six per cage, with 12 hour light-dark cycle. The experimental protocol was followed according to the Guide for Care and Use of Laboratory Animals, which was approved by the Committee for Bioethics in Animal experimentation of the Institute for Problems of Cryobiology and Cryomedicine of the National Academy of Sciences of Ukraine and is subject to the European Convention for the Protection of Vertebrate Animals used for Experimental and Other Scientific Purposes.

The research scheme is presented in the diagram (Fig. 1). The animals were divided into five groups. Cd group was given a single intra-peritoneal dose of CdCl₂, 3 mg/kg of body weight. Cd+ ITT group obtained intratesticular neonatal testis transplanted after Cd pretreatment. Additionally, one group was transplanted with neonatal murine testis under the kidney capsule (UKT group). This group helped to elucidate the phenomenon of immune tolerance. Thus, an intact group (I group) was used that did not get any transplantation or Cd injection.

The age of donors did not exceed 24 hours. These donor mice were sacrificed and testes were taken through the incision of abdominal cavity. Then a small incision in the capsule was made with the spring scissors. The kidney was kept moist with warm sterile saline (PBS supplemented with 100 IU/mL penicillin and 100 µg/mL streptomycin). Then a shallow subcapsular pocket was made with a blunt probe and the graft was placed into the pocket with forceps. Finally, the muscles and skin were layer-by-layer sutured.

The age of donors did not exceed 24 hours. These donor mice were sacrificed and testes were taken through the incision of abdominal cavity. Then a small incision in the capsule was made with the spring scissors. The kidney was kept moist with warm sterile saline (PBS supplemented with 100 IU/mL penicillin and 100 µg/mL streptomycin). **Results**

**Flow Cytometry Analysis.** Cd pretreated animals (Cd and Cd+ ITT groups) were slaughtered by weeks 4, 6, 8 and 12 after Cd administration. In case of Cd+ ITT group these terms corresponded to week 0, 2, 4 and 8 after intratesticular transplantation. Groups that were given transplantsations only (ITT and UKT) were also slaughtered by weeks 2, 4 and 8 after transplantation. Their organs with grafts were examined histologically. Interstitial cell suspension obtained from testes with intratesticular grafts underwent flow cytometric analysis. The testes were decapsulated, trimmed of blood vessels and placed in 15 mL centrifuge tubes with 4 mL DMEM (PAA, Austria) per testis with 0.2 mg/mL collagenase (type I) (Sigma-Aldrich, USA) and 0.1 mg/mL DNase I (Sigma-Aldrich, USA) for 10 min in a thermostat-shaking water bath (90 cycles/min at 34 ºC). 10 mL of collagenase-free DMEM were added to each tube and the seminiferous tubule mass was removed by filtration through doubled, 100-µm nylon mesh. The filtrates were centrifuged at 325 g for 3 min at room temperature. The supernatants were discarded. The residues were re-suspended in 5 mL PBS. The procedure of sedimentation was repeated.

The interstitial cell suspension was incubated with monoclonal antibodies specific to CD11b, CD8 α, CD25 (IL2 receptor α), CD3 conjugated to FITC and CD45, CD4 conjugated to PE (Abcam, UK). 5 µL of antibody dilutions were added to 300 µL of cell suspension. The cells were stained for 30 minutes. Then, the cells in the sample were washed with PBS and analyzed. The immunophenotyping of the testicular cells was done using FACS Calibur flow cytometer (Becton Dickinson, USA).

The testes were fixed, dehydrated in graded ethanol, cleared in xylene and embedded in paraffin wax. The sections were cut at 5 micrometers, stained with hematoxylin and eosin and observed under a light microscope (MEIJU Techno, Japan).

All data were processed by Statistica 6.0 package for Windows (Tulsa, OK, USA), and the results were expressed as median with 25th and 75th interquartile range. The statistical differences between groups’ percentage points were determined using nonparametric Kruskal-Wallis test. Multiple comparisons were tested using Mann–Whitney U-test with Bonferroni correction. The differences were considered reliable at P < 0.05.

The results may provide an insight into the long-term impact of Cd on an organism in order to develop novel treatment approaches for acute and chronic Cd intoxication and for male fertility preservation or restoration.

Fig. 1. The scheme of the research
weeks 8 and 12. Intratesticular transplantation alone caused a noticeable increase in CD11b+ content (Table 1) in ITT group over the whole-time frame of observation. CD45+, CD3+ and CD8+ contents stayed relatively stable by week 2 after transplantation but then demonstrated a sharp rise by week 4 especially in case of CD45+ and CD3+. Intratesticular transplantation resulted in a reliable increase in CD4+ and CD3+ CD25+ cell subpopulation by weeks 4 and 8. The proportions of all studied cells got back to the normal level by week 8 after transplantation.

Combined effect of transplantation and Cd pretreatment elevated the proportions of all cell populations. The I group to the levels of CD45+, CD3+, CD8+, CD4+ was very pronounced by weeks 2 and 4 compared to Cd and ITT groups. Then the proportions of the cells gradually decrease by week 8 after transplantation.

**Histological examination.** In Cd and Cd+ ITT groups, Cd injection resulted in a severe inflammation by the next day. The peritubular capillaries of the testes were engorged with blood. Intratubular edema was present (data were not shown). The germinal epithelium was sloughed. This acute inflammatory process, however, weakened by the fourth week after Cd administration. However, the foci of cellular detritus remained in places of seminiferous tubules and development of fibrous tissue was detected in between the seminiferous tubules. The Cd+ ITT group was subject to transplantation after four weeks of such a Cd injection.

**Table 1**
The proportion of immune cells of testicular interstitial tissue Median and 25th–75th percentile

| Groups          | Subpopulations: | CD11b+ | CD45+ | CD3+ | CD8+ | CD4+ | CD4+ CD25+ |
|-----------------|-----------------|--------|-------|------|------|------|------------|
| I group         | Standard values | 7.48   | 2.75  | 2.05 | 0.76 | 0.75 | 0.01–0.04  |
|                 | 4 week after injection | 2.9    | 2.24  | 1.51 | 0.21 | 0.30 | 0.11–0.15  |
|                 | 6 week after Cd injection | 1.04*  | 3.58  | 1.75 | 0.46 | 0.45 | 0.01–0.02  |
|                 | 8 week after Cd injection | 0.51*  | 4.41* | 2.02 | 0.75 | 0.76 | 0.00–0.00  |
|                 | 12 week after Cd injection | 0.15*  | 1.49  | 0.81* | 0.21* | 0.21* | 0.00–0.00  |

**ITT group**

| Week 2 (6 week after Cd injection) | 13.31* | 34.28* | 32.59* | 18.73* | 8.91* | 0.20* |
| Week 4 (8 week after Cd injection) | 9.20*  | 20.57* | 14.47* | 2.47*  | 2.57* | 0.31* |
| Week 8 (12 week after Cd injection) | 7.10*  | 12.16* | 4.91*  | 2.00*  | 1.53* | 0.09* |

**Cd+ ITT group**

| Week 2 (6 week after Cd injection) | 11.26–14.58 | 30.37–38.37 | 29.55–35.28 | 16.72–20.16 | 8.01–9.95 | 0.16–0.23 |
| Week 4 (8 week after Cd injection) | 8.13–10.21 | 17.34–22.99 | 13.24–16.32 | 2.21–2.85 | 2.10–2.92 | 0.23–0.34 |
| Week 8 (12 week after Cd injection) | 5.55–8.45 | 11.08–13.57 | 4.55–5.45 | 1.79–2.31 | 1.38–1.72 | 0.06–0.13 |

**Note:** The statistical differences between groups’ percentage points were determined using nonparametric Kruskal–Wallis test; multiple comparisons were tested using Mann–Whitney U-test with Bonferroni correction; the differences were considered reliable at P < 0.05; *P < 0.05, statistically significant with respect to I group; #P < 0.05, statistically significant with respect to corresponding values of ITT group.

**Histological examination of neonatal testis before the transplantation**

It showed that it consisted of immature seminiferous tubules having the diameter of 20–30 μm (Fig. 2a). Spermatogonia were at the center of the tubule. Primitive Sertoli cell and singular gonocytes/prospermatogonia were located at the periphery of seminiferous tubules and close to the basal membrane. The lumen of seminiferous tubules was absent. Loose connective tissue was situated in between the seminiferous tubules. It occupied more than a half of the area of cross-sections.

After two weeks of transplantation the steady development of grafts was observed in ITT group (Fig. 2b). The Sertoli cells were lined along the basal region of the tubules. In the ITT group, spermatogonia were localized in the peripheral layer of seminiferous tubules. Interestingly, many seminiferous tubules of the ITT group had advanced populations of spermatogenic cells such as spermatocytes. The formation of luminal cavity was observed in several seminiferous tubules. Intestinal tissue possessed some mature traits: they were tightly adjoined to one another.

The neonatal testis grafts in the Cd+ITT group were less advanced (Fig. 2c). The Sertoli cells were lined along the basal region of the tubules. Some spermatogonia were found on the basal membrane. The seminiferous tubules did not contain either spermatocytes nor other populations of germinal epithelium. The tubules were separated by a wide layer of connective tissue. Although foci of lymphoid infiltrate were not seen in the graft its development seemed to be depressed compared to the ITT group. Vacuoles and desquamated germinal epithelium were seen in almost all tubules of Cd+ ITT group grafts by week 2. The UKT group grafts had remnants of seminiferous tubules by week 2 (Fig. 2d). The lumen of their seminiferous tubules contained nothing. There was cellular detritus in the centers of some seminiferous tubules. Few Sertoli cells were observed on the periphery. Intestinal tissue was degraded. The seminiferous tubules of the ITT group comprised normally shaped Sertoli cells four weeks after transplantation (Fig. 3a). The single spermatogonia were seen in between the Sertoli cells and basement membrane. In the center of seminiferous tubules, desquamated germinal epithelium was present.
Leukocyte infiltration in this interstitial tissue. Detachment of the germinal epithelium from the seminiferous tubules (Fig. 3b). There were no seminiferous tubules in the ITT group grafts by week 4. These grafts had cystic-like cavities in the center of some tubules. Foci of lymphoid infiltration and connective tissue development were shown in places of seminiferous tubules (Fig. 3c). The boundaries between the remnants of the seminiferous tubules and interstitial tissue were blurred.

The interstitial tissue of ITT grafts was thickened. There was also leukocyte infiltration in this interstitial tissue.

As for Cd+ITT group grafts by week 4, their histological appearance showed irregularly shaped Sertoli cells that were lining the seminiferous tubules (Fig. 3b). Detachment of the germinal epithelium from the wall of the seminiferous tubule was observed. The detritus of germinall epithelium was seen in the center of some tubules. Foci of lymphoid infiltration and connective tissue development were shown in between the seminiferous tubules. Dense fibrous capsules formed around the seminiferous tubules. There were no seminiferous tubules in the UKT group grafts by week 4. These grafts had cystic-like cavities in places of seminiferous tubules (Fig. 3c). The boundaries between the remnants of the seminiferous tubules and interstitial tissue were blurred.

The fibrous tissue formed in the grafts.

By week 8, there was no apparent difference in the architecture between seminiferous tubules of the ITT and Cd+ITT group grafts (Fig. 3d, e). These grafts were primarily represented by Sertoli cell-only tubules. The formation of connective tissue took place in between the seminiferous tubules. As for the UKT group by week 8, there was a total replacement of graft by connective tissue (Fig. 3f).

Discussion

CD11b is implicated in various adhesion interactions of monocytes, macrophages and granulocytes as well as in mediating the uptake of complement coated particles. CD11b is also a receptor for fibrinogen, factor X, and ICAM1 (Fendel et al., 2018). CD11b is a family of single chain transmembraneous glycoproteins. It is expressed on cells of the human hematopoietic lineage with the exception of mature red blood cells. It is not detected on differentiated cells of other tissues. CD45 plays an important role in signal transduction, inhibition or upregulation of various immunological reactions (Rheinländer et al., 2018). Of note, macrophages present in the testicular interstitial tissue do not normally express CD45 (Mullen et al., 2003). CD3 is a component of T-cell receptor. The antigen is present on most peripheral blood lymphocytes, 65-85% of thymocytes (De Rose et al., 2013). It plays a role in T-cell receptor-induced growth arrest, cell survival and proliferation. The CD8 antigen is a cell surface glycoprotein found on most cytotoxic T lymphocytes that mediates efficient cell to cell interactions within the immune system (Diao & Pipkin, 2019). The CD8 antigen, acting as a coreceptor, and the T cell receptor on the T lymphocyte recognize antigen displayed by an antigen presenting cell in the context of class I MHC molecules. CD4 is a single chain transmembraneous glycoprotein which belongs to the immunoglobulin superfamily. CD4 is present on a subset of T lymphocytes ("helper/inducer" T cells) and is also expressed at lower level on monocytes, tissue macrophages and granulocytes. The antigen is involved in binding to MHC class II molecules (Sweet et al., 1991). Its intracellular domain is associated with a type of protein tyrosine kinase. CD25 is a part of IL2 receptor present on activated T and B cells, thymocyte subset, pre B cells and T regulatory cells (Vai kunthanathan et al., 2017). Thus, the markers reflect the development of local inflammatory process and cellular response of recipient on foreign tissue grafting.

Acute short-term Cd effect on testicular tissue was thoroughly described by Pak (1988), Maretto et al. (2010) and Ababiku et al. (2019). Our findings corroborate the data: the testes were inflamed immediately after Cd injection. There were multiple hemorrhages observed in testicular parenchyma. Seminiferous epithelium was severely damaged.

However, the acute inflammatory process ended by the fourth week after Cd administration because the levels of potentially pro-inflammatory cells (CD11b+, CD3+, CD8+) were even lower than in the I group. Taking these into account, the fourth week after Cd injection (the time point which was characterized by the damped inflammatory response on Cd injection) was chosen as a suitable moment for intratesticular transplantation and for investigation of long-term effects of Cd. In this case the development of graft tissue can reflect the changes in testicular immunity, hormone production and other functions. Another consequence of the inflammation was the total irreversible damage of host germinall epithelium by week 4 after injection. One other consequence may include specific Cd effects well documented in the literature such as the disruption of tight and gap junction playing a role in maintaining the BTB (Cheng et al., 2011; Zhang & Liu, 2014; Ramos-Treviño et al., 2017). It is not clear to what extent the latter changes are reversible. It is also not well understood how the absence of germinall epithelium may affect testis immunity and other function such as hormone production on a long-term scale after Cd exposure.

The investigation of under-the-kidney capsule versus intratesticular grafts helped establish the fact of immune tolerance. The comparison of the types of transplantations showed that intratesticular transplantation promoted graft survival in both the ITT and Cd+ITT groups. Intratesticularly transplanted grafts represented steady development during the first two week after transplantation. Advanced germ cell populations were seen in the ITT and Cd+ITT groups but not in the UKT group. The UKT group grafts were degrading and being replaced by connective tissue.

Testicular macrophages are the most abundant immune cells residing in the testis, an immune-privileged organ. They exhibit different functions, such as protecting spermatogenesis from auto-immune attack by producing immunosuppressive cytokines and trophic roles in supporting spermatogenesis and male sex hormone production. Testicular macrophages share common core tissue-resident macrophages markers as F4/80, CD11b, CD64, M-CSFR (Gordon, 2002; Gautier et al., 2012; Gentek et al.; 2014; Mossadeq-Keller & Sieweke, 2019). One characteristic of cellular response on the intratesticular transplantation of newborn testes was an increase in the CD11b+ cell content. However, they are characterized by a subdued proinflammatory response, a polarization toward the immunoregulatory and immunotolerant phenotype that enables them to play a relevant role in the functions of the testis. During infection, the characteristic blunted immune response of tissue macrophages is not detected on differentiated cells of other tissues.
phages reflects the need for a delicate balance between a sufficiently strong reaction to counteract invading pathogens, and the prevention of excessive proinflammatory cytokine levels with the potential to disturb or destroy spermatogenesis (Meinhardt et al., 2018). The content of CD11b+ cells remained elevated over a period of observation.

Another characteristic of intratesticular transplantation can be outlined in the following way: groups with intratesticular grafts (ITT and Cd ITT) responded to transplantation by an increase in the subpopulation of CD4+ CD25+ cells. Regulatory T cells (Tregs) have a pheno-
type CD4+ CD25+ mediate tolerance to self-antigens maintaining im-
une homeostasis (Nasr et al., 2005). Defects in the number and func-
tion of Tregs lead to aberrant immune responses to autologous components, thereby causing autoimmune diseases and male infertility (Jacobo, 2018). However, Cd pretreatment resulted in a change in the balance between the CD4+ CD25+ and other cell subpopulations such as CD8+ and CD45+ after intratesticular transplantation. Although both groups with intratesticular transplantation possessed an elevated proportion of Tregs, the heightened level of proinflammatory CD45+ leukocytes and CD8+ T lymphocytes in the Cd ITT group apparently outnumbered Tregs or affected their immunosuppressive properties. Similar effects were described by Jacobo (2018).

Interestingly the obtained data are corroborated with histological appearance of intratesticular grafts. For example, in the Cd ITT group grafts showed less advanced germ cell types (spermatogonia) than in the TT group. They also had sloughed germinal epithelium and vac-
ules by week 2. By week 4, however, in the Cd ITT group the pro-
portion of Tregs cells increased with respect to leukocytes and lympho-
cyes which to some extent suppressed the process of graft rejection. Therefore, intratesticular transplantation showed that Cd pretreatment resulted in a change in the balance of Tregs and other cell populations.

This change manifested over a long period after Cd administration and transplantation (up to week 8) and could be attributed to long-term Cd effects on the testis.

As mentioned above, Cd administration disrupted host semine-
rinous epithelium but there is a considerable body of evidence that the element may influence interstitial compartments, such as Leydig, vascular, immune, and peritubular cells. The testis is especially susceptible to Cd exposure, which may decrease total and free testosterone levels re-
sulting in hypogonadism (Chen et al., 2016; de Angelis et al., 2017). There are also models of Cd induced hypogonadism described (Potikha et al., 1993). Intertitial cells take part in complex signaling interactions with both interstitial and tubular cell populations, which are required for several biological processes, such as steroidogenesis, Sertoli cell function, spermatogenesis, and immune regulation (Heinrich & DeFalco, 1993). Interstitial cells associate with lower testosterone and sex hormone-binding globulin in chinese men. From SPECT-China study, 2014. Biological Trace Element Research, 171(1), 71–78.

Conclusion

Cd pretreatment affected the balance between Treg cells and leuko-
cytes/T-lymphocytes. This was demonstrated with flow cytometry ana-
lysis under intratesticular transplantation. The balance was important for the intratesticular graft development by the second week, which was proved by comparing outcomes of intratesticular transplantations of groups with and without Cd pretreatment. Although the disproportion of cell population affected immune privilege properties, the Cd pretrea-
tested testes were still able to foster graft survival when the non-immune privileged under-the-kidney capsule was not able to do so. It proves that acute Cd intoxication may have a long-term effect on the organism’s health and male fertility.
