Genetic divergence of native palms of *Oenocarpus distichus* considering biometric fruit variables

Gleidson Guilherme Caldas Mendes¹, Mônica Trindade Abreu de Gusmão², Thales Guilherme Vaz Martins¹, Renato Domiciano Silva Rosado³, Rayanne Savina Alencar Sobrinho², Andrei Caique Pires Nunes⁴, Wellington Souto Ribeiro⁵ & José Cola Zanuncio⁶

*Oenocarpus distichus* presents economic, ecological, and dietary potential for pulp market processed *in natura*. Germplasm conservation and genetic improvement depend on genetic divergence studies. The objective was to quantify genetic divergence in a native population of *O. distichus* genotypes based on fruit biometrics. The fruit length and width, fruit mass, pulp and seed, pulp and almond thickness, and pulp yield per fruit were evaluated. All fruit biometric characteristics of *Oenocarpus* palms show genetic variability. Genetic variations among genotypes are essential for predicting heredity and heterosis, which are essential for improving *O. distichus* production. Pulp yield and seed mass were negatively correlated. Almond thickness and pulp, seed mass and transverse diameter were positively correlated. Genetic distances between pair of genotypes ranged from 0.07 to 48.10 with three genetically distinct groups. The seed mass, almond thickness and transverse diameter contributed to genetic divergence. Heritability estimates the genetic control that can be obtained from *O. distichus* germplasm. Correlations between the variable pair reduce the evaluation effort and the resources to measure the genotype allocations in heterogeneous groups presenting high genetic variability. This makes it possible to select individuals for hybridization programs with F1 generation gains. Correlation and relative contribution networks, based on relationships graphical between fruit biometric characteristics, allow the variables selection with less effort and fewer measurements. *O. distichus* fruit biometric characters are efficient to quantify genetic divergence between genotypes.

The genetic diversity of Brazilian Amazonian plants is significant but remains poorly understood. The sites identification for conservation and germplasm collection in this region is a great challenge, especially for some native palm trees¹.

Palm fruits and palm hearts native to the Amazon are consumed by local communities but are poorly known at the national and international levels². *Oenocarpus* spp. plants have economic, ecological and dietary potential and are exploited through extraction by Amazonian communities³⁴⁵.

Six species of the genus *Oenocarpus* spp. are native to Brazil, but not endemic, including *O. distichus* Mart., *O. bacaba* Mart., *O. minor* Mart. and *O. mapora* H. Karten and O. pataua Mart.⁶. *Oenocarpus distichus* (also known as bacaba-de-leque) has high potential in the palm and processed pulp markets, including its use in the production of "bacaba wine", a nutritious energy drink with commercial potential similar to that of *Euterpe oleracea* Mart.⁷.

*Oenocarpus distichus* phytochemicals have phenolic compounds correlated with antioxidant capacity⁸⁹ and vitamin E, riboflavin, insoluble fiber, energy, and minerals, especially potassium and calcium⁸. This plant has oil...

with organoleptic properties similar to those of olive oil and raw material for the food industry with proteins of high biological value (40% more than soy) and adequate to manufacture ice cream and soap.

The genetic diversity in O. distichus native populations, from the morphological characteristics of their fruits, needs to be better understood for germplasm inclusion. This is necessary for breeding programs to conserve native populations in extractive areas. Oenocarpus distichus genetic improvement and conservation programs depend on fruits biometric characterization and genetic parameter studies of genotypes showing promise for germplasm banks and conservation programs of this plant.

Multivariate analyses allow selecting individuals for breeding programs and morphological or molecular characteristic identification to evaluate the divergence of native and exotic plants such as E. oleacea, Theobroma grandiflorum Willd. Ex Spreng., Elaeis guineenses Jacq., and Phoenix dactylifera L. in forest fragments.

Grouping methods, based on prefixed similarity/dissimilarity measures, can identify divergent groups. Group determination, based on a standard, universally, accepted method does not exist, but individuals of the same group should be as homogeneous as possible and different from the others.

Fruit characteristics are important for characterization, individual selection and genotypes choice during recombination cycles. Genetic divergence, important for prospecting in plant breeding programs, allows us to know the available germplasm to evaluate similar or divergent groups to identify hybrid combinations with greater heterozygosity and heterotrophic effect. Genetic divergence will allow us to know the available germplasm to predict combinations with higher heterozygosity so that there will be more possibilities of recovering fruitful Oenocarpus distichus genotypes in the segregant generations. Distribution among groups will allow the early determination of the best combinations and reduces the unneeded crosses number, prioritizing more contrasting groups for obtaining combinations with higher heterosis. Biometric fruit variables differences such as morphological and production are regarded in the dissimilarity quantification. Those genetic variations among Oenocarpus distichus genotypes are essential for predicting heredity and level of heterosis, which are essential for improving Oenocarpus distichus production.

The objective of the present study was to quantify the genetic divergence between Oenocarpus distichus genotypes in a native population in the northeastern region of Pará, Amazon rainforest, Brazil, based on fruit biometric characteristics.

Results

All O. distichus fruit biometric characteristics (F-test < 0.01) show genetic variability (Table 1) with residual variation coefficients (CV) of 6.67% for fruit length (FL) at 15.09% for pulp mass (PM), indicating high experimental precision. The genetic variation coefficient (CVg) values, mainly of the PM, seed mass (SM) and fruit mass (FM) characters, confirmed the genetic variation between the O. distichus genotypes. The relationship between CVg/CVe was greater than 1 for the characteristics fruit width (WF), FM, PM and SM. Matrix inheritance estimates for average ones (h²mp) ranged from 85.38 for pulp thickness (PT) to 96.81 for FM. The mean values of biometric characteristics of O. distichus fruits and Scott-Knott test at 5% probability are given in supplementary information.

The biometry correlation matrix of the O. distichus fruits indicate estimates for the last two eigenvalues near to zero, resulting in two linear relationships determining the harmful effects of multicollinearity (Table 2). The condition number for this matrix indicated NC > 1000, that is, severe colinearity. The eigenvectors, associated with the last two eigenvalues destacados, indicated that the FM and PM characteristics (highest absolute values highlighted in bold) are responsible for multicollinearity. The low NC matrix lower than 100, after the exclusion of the FM and PM variables, indicates weak collinearity (Table 3).

In addition to the CN, small single values were observed for FM (0.0503) and PM (0.0043) and high condition index FM (46.60) and PM (537.90), indicating serious problems caused by multicollinearity. VIF values can also be used to detect the existence of multicollinearity. The FM and PM variables presented VIFs of 12.53 and 101.37, respectively. The existence of at least one VIF with a value greater than 10 is sufficient for the regression coefficients associated with these values to be highly influenced by multicollinearity, indicating that these variables must be removed from the analyzes.
The PM characteristic correlated with FL and PT and FM with AT and SM, all above 70% (Fig. 1B). The correlation pattern between the fruit biometric characteristics did not vary, even after excluding the FM and PM variables that caused multicollinearity (Fig. 1C,D). The characteristics PY and SM (Fig. 1C) and AT, SM, PT and PY (Fig. 1D) correlated, negatively, with a magnitude of 42% and above 70%, respectively.

The genetic variability between the O. distichus genotypes, for all fruit biometric characteristics, indicates that the germplasm of this plant can be collected in the region studied. Additionally, the selection, based on any of the eight features, provides genetic advantages to differentiate individuals within the same population, due to the cross between genetically different individuals causing greater heterotrophic effect. The variability between the genotypes can be attributed to the data quantitative nature, polygenic, controlled by many genes and is important in ex situ genetic conservation, due to increasing the effective population size and reducing the mortality caused by inbreeding. The efficiency of these biometric characteristics to distinguish genotypes from the family Arecaceae was confirmed with similar results for E. oleracea. The CV_p/CV_e ratio (>1) and the high h²mp values, confirm the variability and the genetic control of fruit characteristics, allowing selecting and recombining the most promising O. distichus genotypes. CV_p/CV_e values, greater than 1, indicate gains in selection and that the environment has a low impact on the characteristics measured. These values should be considered in breeding and conservation programs for this palm. Genetic variations in native populations are important to obtain...

| Groups | Palms |
|--------|-------|
| I      | 3 5 7 1 6 5 10 12 11 9 13 4 |
| II     | 2 14 |
| III    | 8     |

**Table 5.** Dissimilarity groups formed by the Tocher method from the generalized distances of Mahalanobis estimated for *Oenocarpus distichus* genotypes.
years of low productivity and maintenance of at least 50% of them on the palms are important to maintain consumption by wildlife. The high multicollinearity values caused by FM and PM were expected, because they are characteristics collinear with PY and common in studies involving fruit characteristics, as reported for *Theobroma grandiflorum* Willd. Ex Spreng. and *Plukenetia volubilis* L. However, they should be excluded from the analyses, because they may lead to false biological interpretations and errors in the genotype selection process, due to the lack of precision in parameter estimation.

**Figure 2.** Dendrogram obtained by unweighted pair group method with arithmetic mean (UPGMA) based on Mahalanobis distance of fifteen *Oenocarpus distichus* genotypes with the cut-off point determined according to and cophenetic correlation coefficient (CCC). Dendrogram generated with GENES (GENES - a software package for analysis in experimental statistics and quantitative genetics. http://arquivo.ufv.br/dbg/genes/genes_Br.htm).

**Figure 3.** Canonical variable 2D biplot related to six fruits traits of fifteen *Oenocarpus distichus* genotypes. Cophenetic correlation coefficient, distortion and stress of 96%, 16% and 20%, respectively. 2D biplot generated with GENES (GENES - a software package for analysis in experimental statistics and quantitative genetics. http://arquivo.ufv.br/dbg/genes/genes_Br.htm).

**Table 6.** Relative contribution of variables (CR), eigenvalue estimates (AV), accumulated variance percentages (AC%) and weighting coefficients (eigenvectors) associated with each variable by canonical ones. FL- fruit length; WF- fruit width, SM- seed mass; PT- pulp thickness; AT- almond thickness and PY- pulp yield per fruit.
The correlations between the fruit biometric variables, visualized by graphic network analysis, show the potential of this technique to select variables that reduce the evaluation time and resources for measurement in *O. distichus* breeding programs. This confirms their wide use to relate characteristics of interest and to enable greater effectiveness in the divergent selection and superior *O. distichus* genotypes, as reported for *Capsicum* spp. Species, *Passiflora edulis* Sims, and *Cocos nucifera* L.

The large number of genotypes with genetic distances above the general average confirms genetic divergence and suggests the crosses’ ability to explore additive genetic values in *O. distichus* individuals and consequently their heterosis in subsequent cycles, as reported for *P. volubilis*9,32. Similar groupings with the Tocher and UPGMA methods, the consistent genetic divergences between genotypes 2, 5 and 8 and the low number of groups may indicate a common ancestry for this plant in the region32, similar to that reported for *Bactris gasipaes* Kunth.33, *E. olaracea* Mart.11 and *T. grandiflorum* Wildl. Ex Spreng.12 with 3, 5 and 3 groups, respectively. Matrix separation into heterogeneous groups may indicate distinct gene pools for controlled hybridizations and reciprocal recurrent selection and, therefore, be interesting for genetic improvement14. Additionally, the grouping restricts the crosses number, reducing costs and increasing genetic gains in subsequent cycles, due to the reduced in breeding coefficient in the population by excluding similar individuals32.

The concentration of a large part of the total variance in the first two canonical variables (above 80%) shows that it is possible to study the genetic divergence between *O. distichus* genotypes by geometric distances in scatter plots34, as reported for genetic divergence in *C. nucifera*22. The projection of dissimilarity measures in 2D projection representation and use of dendrograms are acceptable when the correlation value between measures of original distances and a graphics is higher than 0.9 and values of distortion and stress lower than 20%35. In a graphic dispersion of canonical variables the grouping was compatible with the ones grouped by Tocher's method. The bigger contribution of the SM, AT and WF characteristics to genetic divergence is important in selection programs, for being more responsive in the superior genotype identification32. The variable FL, even presenting lower relative contribution to genotype divergence, should not be removed from the analyses because it is easy to determine using non-destructive methods36. In addition, most of the genotypes that had lower FL showed higher yields of pulp (supplementary information). This result is in agreement with what is reported in the literature for *E. olaracea*, where higher fruit lengths result in lower pulp yields37.

Conclusions

Biometric fruit characteristics are efficient to quantify genetic divergence between *Oenocarpus distichus* genotypes. The contribution of the seed mass, almond thickness and fruit width, for genetic divergence, is higher and for this reason, these parameters should be prioritized in selection processes. Correlation networks facilitate the visualization of the correlations between the variables and the potential to choose those requiring less time for evaluation and fewer resources in the measurements in *O. distichus* breeding programs.

Grouping methods are effective in allocating *O. distichus* genotypes, in different groups, and should be used to maintain the genetic variability, conservation and selection of genotypes of this plant for breeding programs in native populations.

Material and Methods

Study area characterization. Fruits were collected from *O. distichus* native genotypes in an Amazonian forest fragment in the municipality of Oeiras do Pará, northeast of Pará, Brazil (02°00’11”S; 49°51’16”W) (Fig. 4). The climate is Ami type, according to Köppen’s classification, with 2,334 mm year⁻¹ annual precipitation concentrated from December to March. The average annual temperature and relative air humidity is 83% and 29 °C, respectively38. The original forest types are dense low plateau forests and dense alluvial, with high populations of the genus *Oenocarpus*.

Plant material. *Oenocarpus distichus* genotypes, with mature fruits, were selected and those in good phytosanitary conditions were collected in April 2016, based on fruit productivity and with a minimum distance of 150 meters between genotypes. The fruits of each genotypes were identified, packed in plastic bags, placed in a Styrofoam box with ice and transported to the genetics and improvement laboratory of the Universidade Federal Rural da Amazônia, Campus Belém, Pará.

Biometric and statistical analysis. The statistical design was entirely random, with 15 genotypes and 14 fruits collected from each one. The length (FL), width (WF) (mm) and mass (FM) of fruits, pulp (PM) and seed (SM) (g) mass; and pulp (PT) and almond (AT) (mm) thickness were evaluated (Fig. 5). The pulp yield per fruit (PY) was obtained by the ratio between the FM and PM. The masses were determined on a digital scale (0.001 g) and the length and width using pachymeter (0.01 mm).

Genetic variability between genotypes was tested with analysis of variance (ANOVA, using a Fisher’s test (F-test) at 1% probability. The genetic parameters heritability (h²_ips), coefficient of genetic variation (CV %) and variation coefficient (CVv,%) were also determined. The means were grouped by Scott-Knott method39.

Possible linear relationships in the residual correlation matrices were obtained with multicollinearity test40. The multivariate analysis of *O. distichus* fruit data was performed using canonical variable techniques41. Dissimilarity was determined with the Mahalanobis generalized distance42 with grouping technique. The Tocher optimization method43 with the divergence measure mean per group lower than those between any other, and using the arithmetic mean method between unweighted pairs (UPGMA-Unweighted Pair Group Method with Arithmetic Average)43 based on Mojena30 delimited the groups. The relative contribution of the characteristics to genetic divergence was quantified by Mahalanobis generalized distances using the Singh method44.

Relationships between the fruit biometric evaluations were represented graphically with correlation networks. The phenotypic correlation were analyzed by weighted matrix with connections between the variables....

Acknowledgements

The authors gratefully acknowledge Dr. Cosme Damiao Cruz, professor in the Department of General Biology (DBG) at the Federal University of Viçosa - Brazil, for his valuable assistance. Dr. Cruz provided excellent advice for statistical analyses and offered good suggestions about genetic diversity using GENES Software (https://www.facebook.com/GenesNews/). We also acknowledge Coordenação de Aperfeiçoamento de Pessoal de Nível Superior (CAPES) by granting scholarship to authors. This study was financed in part by the Coordenação de Aperfeiçoamento de Pessoal de Nível Superior – Brasil (CAPES) – Finance Code 001.

Author Contributions

G.G.C.M. and M.T.A. de G. conceived and designed the elements of this study. R.S.A.S. and G.G.C.M. contributed to field samplings and analyses biometrics. R.D.S.R. and G.G.C.M. developed the statistical analyses and created all of the tables and figures presented in this manuscript. W.S.R. and A.C.P.N. contributed to reviewing and editing. The Manuscript was written mainly per G.G.C.M., T.G.V.M., R.D.S.R. and J.C.Z. although all authors read and approved the final version of the manuscript.
