The highest qubit Ardehali inequality violation with 203 standard deviations is first experimentally demonstrated using the hyper-entangled four-photon-eight-qubit Greenberger-Horne-Zeilinger (GHZ) state. Moreover, we experimentally investigate the robustness of the Ardehali inequality for the four-, six-, and eight-qubit GHZ states in a rotary noisy environment systematically. Our results first validate the Ardehali’ theoretical statement of relation between violation of Ardehali inequality and particle number, and proved that Ardehali inequality is more robust against noise in larger number qubit GHZ states, and provided an experimental benchmark for us to estimate the safety of quantum channel in the noisy environment.

Nonlocality is one of the most surprising and important features of quantum physics. It is firstly referred by Einstein, Podolsky and Rosen (EPR), and has been receiving an enormous attention and interest of scientists since Bell designed an inequality to expose it. Bell-type inequalities against local realism (LR) model not only plays a crucial role in fundamental research, but is also at the basis of nearly all quantum information protocols applying process, such as proving the security of quantum cryptography, the reduction of communication complexity, the estimates for the dimension of the underlying Hilbert space, and the entangled games. For example, in Ekert’s quantum key distribution (QKD) protocol, one encrypts the key into the non-compatible qubit and the security of quantum cryptography is based on maximal violation of local realism, that is, the greater of the violation value means that the QKD scheme is more security. So, it is useful to know the largest violation of a given Bell inequality that quantum mechanics makes possible, and, in addition, which quantum state will produce this violation.

What’s even more exciting is Mermin and Ardehali showed that quantum mechanics (QM) can violate the multi-particle Bell-type inequalities imposed by LR by an amount that grows exponentially with particle number, that is, going to higher entangled systems the conflict between QM and LR becomes ever stronger. Over the past years, great efforts have been devoted to generate and manipulate more qubits and get the larger violation between QM and LR. However, the effect of quantum mechanics violates the Bell inequalities by an amount that grows exponentially with the number of particles is difficult to observe in real experiments because the low multiphoton coincidence count rate and the higher double-pair emission noise effect. To the best of our knowledge, the highest qubit number experimentally used to demonstrate to the violation of the multi-particle Bell-type inequalities is only six by now. Fortunately, one can encode quantum information not only in the polarization of a single photon, and in its spatial modes, arrival time or orbital angular momentum as well. Obviously, using the hyper-entangled technology, one can effectively achieve higher qubit entanglement states, which significatively reduces the decoherence problems and dramatically increases the efficiency of detecting EPR elements of reality. So, hyperentangled photonic states have been experimentally realized, and shown to offer significant advantages in quantum super-dense coding, efficient construction of cluster states and multiqubit logic gates.

Moreover, the robustness of multi-bit hyper-entangled system with noise has almost no further research. As we all know, in realistic applications, pure entangled states become mixed states due to different types of noise, which will lead to the failure of the information processing. It is lucky that the violations of Bell inequalities provide a method to characterize the robustness of the entanglement against noise. Thus, the experimental investigations of the robustness of Bell’s inequality of multi-particle hyperentanglement states have important physical significance and application value.
and first proved that the Ardehali inequality is more robust in larger mentally investigated the robustness of the Bell-type inequality for 203 standard deviations. Most importantly, we systematically experimented the highest qubit (eight qubits) Bell inequality violation with photons’ polarization and spatial degrees of freedom, we demonstrated the highest qubit (eight qubits) Bell inequality violation with 203 standard deviations. Most importantly, we systematically investigated the robustness of the Bell-type inequality for the four, six, eight-qubit GHZ states in a rotary noisy environment, and first proved that the Ardehali inequality is more robust in larger number bits GHZ states.

Results

Theoretical model. Using the Bell’s theorem, Mermin\(^7\) derived an n-particle Bell inequality, and Ardehali derived an optimized Bell inequality for an n-particle system in a GHZ state\(^8\). Consider an n-particle GHZ state \(|\Phi_n\rangle=|H\ldots H H\ldots H\rangle+|V\ldots V V\ldots V\rangle\sqrt{2}\), where \(H\) and \(V\) are horizontal and vertical polarization of i photon. According to the local realism assumption, the nonlocal character of the state \(|\Phi_n\rangle\) can be characterized if defined the operator \(A\) as \(A=A_1+ A_2\), with

\[
A_1 = \left(\sigma_1^x\sigma_2^y\sigma_3^z + ... + \sigma_1^{(n+1)}\sigma_2^{(n+1)}\sigma_3^{(n+1)}\right) - \left(\sigma_2^x\sigma_3^y\sigma_1^z + ... + \sigma_2^{(n+1)}\sigma_3^{(n+1)}\sigma_1^{(n+1)}\right)
+ \left(\sigma_3^x\sigma_1^y\sigma_2^z + ... + \sigma_3^{(n+1)}\sigma_1^{(n+1)}\sigma_2^{(n+1)}\right) - \left(\sigma_1^x\sigma_2^y\sigma_3^z + ... + \sigma_1^{(n+1)}\sigma_2^{(n+1)}\sigma_3^{(n+1)}\right) \left(\sigma_{a}^{n} - \sigma_{b}^{n}\right),
\]

here \(\sigma_{a}\) and \(\sigma_{b}\) are defined as \(\sigma_{a} = (\sigma_{x} + \sigma_{y})/\sqrt{2}\), and \(\sigma_{b} = (\sigma_{x} - \sigma_{y})/\sqrt{2}\), respectively. Using the generalized Clauser-Horne-Shimony-Holt lemma\(^9\), the upper bound of the function \(F\) can be got according to the assumption of LR

\[
F \leq \begin{cases} 2^{n/2}, & n \text{ (even)} \\ 2^{(n+1)/2}, & n \text{ (odd)} \end{cases}
\]

In comparison, the expected value of \(A\) standard rules of QM can be calculate as

\[
\langle \Phi_n | A | \Phi_n \rangle = 2^{n-1/2}.
\]

It can be seen that quantum theoretic value exceeds the limit imposed by the premises of EPR by an exponentially large amount of \(2^{n-20/3}\) for \(n\) odd or \(2^{n-10/3}\) for \(n\) even.

For eight qubits states, the Ardehali operator can be shown as

\[
A = \left(\sigma_1^x\sigma_2^y\sigma_3^z + ... + \sigma_1^{(n+1)}\sigma_2^{(n+1)}\sigma_3^{(n+1)}\right) - \left(\sigma_2^x\sigma_3^y\sigma_1^z + ... + \sigma_2^{(n+1)}\sigma_3^{(n+1)}\sigma_1^{(n+1)}\right)
+ \left(\sigma_3^x\sigma_1^y\sigma_2^z + ... + \sigma_3^{(n+1)}\sigma_1^{(n+1)}\sigma_2^{(n+1)}\right) - \left(\sigma_1^x\sigma_2^y\sigma_3^z + ... + \sigma_1^{(n+1)}\sigma_2^{(n+1)}\sigma_3^{(n+1)}\right) \left(\sigma_{a}^{n} - \sigma_{b}^{n}\right)
\]

Experiment model. Here we experimentally observed violation of Bell inequality in case of eight qubit GHZ state. The four-photon-eight-qubit hyperentangled state exhibit maximal both in polarization and spatial degrees of freedom, which can be shown as

\[
|GHZ_8\rangle = \frac{1}{\sqrt{2}}(|HHHHH'H' H'H'\rangle + |VVVVV'V' V'V'\rangle)
\]
Figure 2 | Experimental results of expectation values of $M_k^a$. The settings are measured in 30 minute. Error bars indicate one standard deviation deduced from propagated Poissonian counting statistics of the raw detection events. (A), the theoretical value. (B), the experimental value.

here $H$ and $V$ denote horizontal and vertical polarization and $H'$ and $V'$ label two orthogonal spatial modes of the photons.

The first step to create an eight qubit GHZ state is produce a four photon entangled GHZ state by combining two polarization entangled pairs into a polarization beam splitter (PBS) which produced from SPDC process in BBO. The experimental setup is shown in Fig. 1a and the operating steps are similar to Refs. 18, 26, 27. In which two pairs of entangled photons are produced by spontaneous parametric down-conversion$^{28}$ in the state $(|H_1H_2\rangle + |V_1V_2\rangle)/\sqrt{2}$ in paths 1–2 and $(|H_3H_4\rangle + |V_3V_4\rangle)/\sqrt{2}$ in paths 3–4, respectively. The photon 2 is combined with photon 3 on a polarizing beam splitter (PBS). When the polarization of the two photons is identical, the four-photon GHZ entanglement state $(GHZ)_p^4 = (|H\rangle^\otimes 4 + |V\rangle^\otimes 4)/\sqrt{2}$ is prepared.

Then, four qubits in spatial modes are added to construct eight-qubit cat state. Consider a polarized single-photon qubit in the state $\alpha|H\rangle + \beta|V\rangle$ that passes through a PBS (see Fig. 1b). The PBS separates the photon into two possible spatial modes $H'$ and $V'$, according to their polarization $H$ and $V$, respectively. The state of this single photon can now be written as $\alpha|HH'\rangle + \beta|VV'\rangle$, an entangled state between its polarization and spatial degree of freedom. Thereby, the hyper-entangled 8-qubit GHZ state (6) can be created.

A noisy quantum channels $R_a(\pm \theta)$ (see Experimental result section) is experimentally simulated by using one half-wave plate (HWP) sandwiched with two quarter-wave plates (QWPs)$^{29}$ (see Fig. 1c). $R_a(\pm \theta) = \left( \begin{array}{cc} \cos 2\theta & \mp i \sin 2\theta \\ \mp i \sin 2\theta & \cos 2\theta \end{array} \right)$ (7)

The operation for qubit i with probability $\lambda$ i.e. noisy intensity is given by$^{30}$, here $\lambda$ is equivalent for every one of the qubits (The noise is only generated on the polarization qubits). The HWP is switched angles $\theta$ and the QWPs are set at $0^\circ$ with respect to the vertical direction. In this way, the noisy quantum channel can be engineered with intensity $\lambda = \sin(2\theta)$. The measurement of polarization qubits is performed using HWPs, QWPs and Polarizers as shown in Fig. 1d. We measure the spatial qubit by using an optical interferometer which combine the two pathes onto a non-polarizing beam splitter and controlling the relative phase with an adjustable delay between these two paths (see Fig. 1b).

Discussion

To verify that $|H\rangle^\otimes 4 |H'\rangle^\otimes 4$ and $|V\rangle^\otimes 4 |V'\rangle^\otimes 4$ are indeed in a coherent superposition, the measurement in the basis $|H\rangle \pm e^{i\phi}|V\rangle$ is preformed, where $\phi = k\pi/(k = 0, 1 \ldots 7)$. The expectation values of the observable $(M_k^a)^{\otimes 4} = (\langle H | M_k | H \rangle)(\langle V | M_k | V \rangle)$ are shown in Fig. 2. From the experimental result in Fig. 2, we can further calculate the fidelity of the 8-qubit cat state and confirm the presence of genuine multi-particle entanglement. For the 8-qubit GHZ state, the fidelity can be measured using the operator $\mathcal{B} = 1/2 \left( \langle H | H \rangle + \langle H | H \rangle^\otimes 4 + \langle V | V \rangle + \langle V | V \rangle^\otimes 4 \right) + 1/16 \sum_{k=0}^{7} (-1)^k \langle M_k \rangle^\otimes 8$. According to the data shown in Fig. 2, the fidelity observed for the state prepared in our experiment is $(79.6 \pm 0.5)\%$, which is greatly exceed the minimum bound of 50%$^{31}$. Thus, with high statistical significance, genuine n-qubit entanglement of the GHZ states created in our experiment is confirmed. Furthermore, we give the measurement results in the $|H\rangle/|V\rangle$ basis, as shown in Fig. 3 a, b, and c for $|\Phi\rangle^\otimes 8$, $|\Phi\rangle^\otimes 8$, and $|\Phi\rangle^\otimes 8$, which show that the signal-to-noise ratio (defined as the ratio of the desired components to that of the other non-desired ones) is about 11:1, 8.97:1, and 7.04:1 respectively.

In the following, let us analyze the QM predictions for the eight-qubit GHZ state (6). As the polarization states of a photon are a realization of a qubit, one can represent it as $|H\rangle$ and $|V\rangle$. That is,
they can be treated as the two eigenvectors of Pauli operator $\sigma_x$, with eigenvalues $+1$ and $-1$, respectively. Adopting the methods of Refs. 26, we consider measurements of linear polarization $H/V$, and $+/\sim$ where $|+\rangle=(|H\rangle+|V\rangle)/\sqrt{2}$ and $|-\rangle=(|H\rangle-|V\rangle)/\sqrt{2}$, or of circular polarization $R/L$, where $|R\rangle=(|H\rangle+i|V\rangle)/\sqrt{2}$ and $|L\rangle=(|H\rangle-i|V\rangle)/\sqrt{2}$, can be represented as the two eigenstates of Pauli operator $\sigma_x$ with eigenvalues $\pm 1$. For the convenience of presentation, we define a measurement of $+/\sim$ linear polarization as an $x$ measurement and one of $R/L$ circular polarization as a $y$ measurement.

The conflict between the quantum predictions for the GHZ states and local realism can be shown via violation of a suitable Ardehali inequality. In this case taking account of the errors is straightforward. A number of inequalities for $n$-particle GHZ states have been derived,32,33. According to the optimal Bell inequality for eight-qubit GHZ state, LR imposes a constraint on statistical correlations of polarization measurements on the eight-qubit system as the following

$$\left|\langle \mathcal{A} \rangle_{LR} \right| \leq 16$$

QM predicts $\left|\langle \mathcal{A} \rangle_{QM} \right| = 128\sqrt{2}$ with a maximal violation of the constraint of LR by an exponential factor of $8\sqrt{2}$. To measure the expectation value of $\mathcal{A}$, we need to perform one hundred and twenty eight measurements such as $\sigma_x^1\sigma_x^2\ldots\sigma_x^n$ measurement on qubit 8 is obtained if we insert in its path a quarter wave plate, whose optical axis is set at 45° with respect to the horizontal direction. Then, the two eigenstates of operator $\sigma_x$ are converted into linear polarizations which are polarized along the directions of 22.5° and 67.5°. In the same way, the two eigenstates of operator $\sigma_y$ can be converted into $-67.5°$ and 22.5° linear polarizations. Substituting the experimental results into the left-hand side of inequality gives $\left|\langle \mathcal{A} \rangle_{Exp} \right| = 107.2 \pm 0.45$ which violate the inequality (8) by over $S = 202.8$ standard deviations, hence demonstrating the largest conflict between QM and LR using an eight qubits hyper-entangled GHZ states.

Next, we experimentally investigate the robustness of the Ardehali inequality for the eight-qubit GHZ states in noisy environment. We define $\gamma$ as the violation of the Ardehali inequality and the $\gamma = (B) - C_{LR}$, here $C_{LR}$ is the up threshold of one inequality for local realism. Then the standard deviations of an entanglement test can be defined as:

$$S = \gamma / \mathcal{E}$$

Table I | Experimental values of the fidelity, the violation, the statistical error, and the standard deviation of states for different values of $\theta$, $\lambda$, $V$, $\mathcal{E}$, $S$, and $F$ represent the values of rotary noise, violation, statistical error, standard deviation and fidelity correspondingly. Each setting $\sigma_x^1\sigma_x^2\ldots\sigma_x^n$ in the Bell inequality is measured for 1800 s, $\sigma_x^1\sigma_x^2\ldots\sigma_x^n$ for 900 s, and $\sigma_x^1\sigma_x^2\sigma_x^3\sigma_x^4$ for 600 s, respectively. The average total count number for each inequality is about 4000 for eight-bits, 6500 for six-bits, and 12000 for four-bits. The error represents one standard deviation deduced from propagated Poissonian counting statistics of the raw detection events.

deviation at different noise levels. As a comparison, we give the results of four-bits and six-bits respectively. From the results shown in Table I, it can be seen that with different noise levels the experimental results of the violation, the standard deviations of the Ardehali inequality decrease accordingly. When \( \theta = \pm 0 \), the standard deviations of the Bell inequality in our hyper-entangled 8-qubit states is \( \Delta = 202.8 \). Moreover, when \( \theta \approx 14^\circ \) the measured value of Bell operator will not violate the Ardehali inequality. It is worth pointing out that the noise level of \( \theta = 14^\circ \) is three times of four photos GHZ states and twenty times of three photos GHZ states, and at this noise level the Ardehali inequality still deviate LR verdict with \( \Delta = 2.8 \) standard deviations. It proves that the Ardehali inequality in hyper-entangled eight-qubit GHZ states is more robust against stronger noise.

It should be pointed out that the generation of the hyper-entangled state and the observation of the Ardehali inequality using hyperentanglement implies that some of the qubits are carried by the same photon, and, therefore cannot be spatially separated. So our setup cannot be used to close the locality loophole. However, the higher dimension entanglement state is helpful to relax the detection efficiencies required for closing the detection loophole in Bell tests. At the same time, in both approaches, a good measure of nonlocality is the ratio between experimental value and the maximal possible value allowed by the local realistic theories. This measure is related both to the number of qubits needed to communicate nonlocally in order to emulate the experimental results by a local realistic theory, and also to the minimum detection efficiency needed for a loophole-free experiment. In this sense, a higher value of this ratio, we experimentally demonstrated, is a significant step toward a loophole-free Bell test.

In summary, using the hyper-entangled four-photon-eight-qubit GHZ states generated by exploiting both the photons’ polarization and spatial degrees of freedom, we experimentally demonstrate the highest qubit Ardehali inequality violation with 203 standard deviations. It is important to point out that the higher violation is a basis for some quantum information processing process such as QKD. Moreover, we experimentally investigated the robustness of the Ardehali inequality for the four, six, eight-qubit GHZ states in a rotary noisy environment systematically and first proved that the Ardehali inequality with a higher qubit is more robust against noise. Our work, besides its significance in quantum foundations, could also be applied to investigate the basic quantum-information processing such as quantum computation with linear optics, topological error correction and quantum metrology and so on.

**Methods**

**Generation of the hyper-entangled four-photon-eight-qubit GHZ states.** A mode-locked Ti:sapphire laser outputs an infrared (IR) light pulse with a central wavelength of 780 nm, a pulse duration of 100 fs and a repetition rate of 80 MHz, which passes through a LiB\(_3\)O\(_3\) (LBO) crystal and is converted to ultraviolet (UV) light pulse with a central wavelength at 390 nm and average power is 250 mW. Behind the LBO, five dichroic mirrors are used to separate the mixed IR and UV components. The ultraviolet light is focused on two \( \beta \)-barium borate (BBO) crystals to produce two pairs of entangled photons. Prisms are used to ensure that the input photons arrive at the PBS\(_2\) at the same time. Finally they are detected by fiber-coupled single-photon detectors and the coincidence events are registered by a programmable multichannel coincidence unit. Conceptual interferometer for implementation and analysis of hyper-entanglement. An incoming photon is split into two possible spatial modes by the PBS with regard to its polarization forming an Einstein-Podolsky-Rosen-like entangled state between the photons’ spatial and polarization degrees of freedom. A Mach-Zehnder-type interferometer with an NPB at 580 nm, \( \text{Sao}038088 \), CASTECH Co.is used to coherently measure the spatial mode qubit, and subsequently at both of its output ports conventional polarization analysis is carried out. QWP: quarter-wave plate; HWP: half-wave plate. The high visibility and the long-term stability (10 hour) of one interferometer used in our experiment are shown in Fig. A.
