ABSTRACT

Purpose: The potential mechanisms of hamstring strain injuries in athletes are not well understood. The study, therefore, is aimed at understanding hamstring mechanics by studying loading conditions during maximum-effort overground sprinting. **Methods:** Three-dimensional kinematics and ground reaction force data were collected from 8 elite male sprinters sprinting at their maximum effort. Maximal isometric torques of hip and knee were also collected. Data from the sprinting gait cycle was analysed via an intersegmental dynamics approach and the different joint torque components were calculated. **Results:** During the initial stance phase, the ground reaction force passed anteriorly to the knee and hip, producing an extension torque at the knee and a flexion torque at the hip joint. Thus, the active muscle torque functioned to produce flexion torque at the knee and extension torque at the hip. The maximal muscle torque at the knee joint was 1.4 times the maximal isometric knee flexion torque. During late swing phase, the muscle torque counterbalanced the motion-dependent torque and acted to flex the knee joint and extend the hip joint. The loading conditions on hamstring muscles were similar to those of the initial stance phase. **Conclusion:** During both initial stance and late swing phases, the large passive torques at both the knee and hip joints acted to lengthen hamstring muscles. The active muscle torques generated mainly by the hamstrings functioned to counteract those passive effects. As a result, during sprinting or high speed locomotion, the hamstring muscles may be more susceptible to a high risk of strain injury during these two phases.

**Key Words:** RUNNING BIOMECHANICS, MUSCLE STRAIN, LOAD CONDITION, JOINT TORQUE, INTERSEGMENTAL DYNAMICS
Introduction

Hamstring strain injury is one of the most common injuries among athletes in sports such as sprinting, soccer, or rugby (14, 23, 33). It can not only cause great pain on stretching or contracting muscles, but also have significant physiological and psychological effects on an athlete’s performance. Although many studies have been conducted to reveal the underlying mechanisms of hamstring strain injuries, it is still in dispute that whether the hamstrings are susceptible to injury during the stance phase or swing phase of the sprinting stride cycle, or both of them (14, 21). The underlying mechanisms of hamstring injuries are not well understood.

Mann and colleagues (17, 18) firstly speculated that early stance was the highest risk period, because their results showed that both knee flexion and hip extension moments reached the greatest value in the early ground contact phase, indicating that the hamstring muscles group may be primarily responsible for generating the main force during this phase. However, the hamstring mechanics of the knee flexion moment during initial stance phase remained unclear in their study.

Many subsequent researchers have rejected Mann's argument, preferring the hypothesis that muscle strains occur during eccentric contractions. They used musculoskeletal models to study hamstring function during running (4, 5, 25, 29, 30). They found that the bi-articular hamstrings reached maximal lengthening, produced peak force, and performed much negative work during late swing phase of the stride cycle and concluded that the bi-articular hamstrings were at greatest risk of injury in this period of the stride cycle. Heiderscheit et al. (7) and Schache et al. (23), also considered neuromuscular latencies and electromechanical delays in pre-injury and injury trials. Results from these studies indicated that the stimulus for the injury must
have occurred prior to foot-strike during the swing phase. However, the exact dynamic contributions (such as motion, inertia, external force) to the stimulus are not very clear.

Yu et al. (35) reported that the peak eccentric contraction speeds of the hamstring muscles were significantly greater during the late swing phase than during the late stance phase. However, the hamstring muscle-tendon lengths at the peak eccentric contraction speeds were significantly greater during the late stance phase than during the late swing phase. Hence the late stance phase and late swing phase were identified as the potential phases for hamstring muscles strain injury. But this study was conducted during an acceleration phase of overground sprinting.

In summary, most of the previous studies are based on the clinical muscle strain assumption, despite experimental muscle strains also being able to be produced during concentric (shortening) contractions (31). Besides, some studies focused on the acceleration phase rather than the maximal-speed phase of sprinting (35), or used a treadmill rather than overground running (4, 5, 23, 29, 30). Although the treadmill is a moderate tool for assessment of running biomechanics, the parameters measured with a treadmill are not equivalent to those measured for overground running and may possibly lead to inadequate conclusions about overground running(19, 27). Furthermore, limited attempts have been made to measure ground reactions during overground sprinting (12, 17, 18, 20), and few prior studies that have used such data to estimate hamstring kinetics during stance (5, 25). For these reasons, the potential mechanisms of hamstring strain injuries in athletes are still not well understood.

This study was aimed at understanding hamstring mechanics by studying loading conditions during maximum-effort overground sprinting. On the basis of the previous studies, we hypothesized that there would be greater hamstring strain risk during both initial stance and late swing phases, compared to other phases of the overground sprinting gait cycle. Especially, an
intersegmental dynamics approach was used to evaluate hamstring kinetics at both the knee and hip joints during the entire gait cycle of elite athletes. This would reveal how the active and passive joint torque components affect the hamstring injury risk.

Methods

Subjects

Eight male elite sprinters (age 21.1 ± 1.9 yrs; mass 74.7 ± 4.1 kg; height 181.5 ± 3.9 cm) (all mean ± SD) participated in this study. The sprinters' best performance records for 100 m ranged from 10.27 to 10.80 seconds. Subjects were free of musculoskeletal injuries of the lower extremity at least 6 months prior to the study. This study was approved by the local ethical committee of Shanghai University of Sport, and all participants gave informed written consent prior to testing.

Data collection

An isokinetic dynamometer (Con-Trex PM1/MJ, CMV AG Corp., Zurich, Switzerland) was used to measure subjects' maximal isometric knee joint flexion and extension torque prior to the sprinting trials. During the sprinting trails, 57 reflective markers were placed on the subjects' anatomic landmarks based on the marker set-up used in our earlier study (8). Three-dimensional kinematic data were collected at a sampling rate of 300 Hz via eight high resolution cameras (Vicon MX, Oxford, UK). The calibration volume for kinematics collection was 10.0 m long, 2.5 m high, 2.0 m wide and located 40 m away from the starting line. Ground reaction forces (GRFs) were collected with a recessed force platform (Kistler 9287B, 0.6 m × 0.9 m; Kistler Instruments Corp., Winterthur, Switzerland). The force signals were amplified and recorded in the Vicon system at a sampling rate of 1200Hz. After sufficient warming up, the subjects wearing spiked shoes performed maximal-effort sprinting on the synthetic track. Each subjects performed 3-4
trials with sufficient rest intervals. One of the trails containing valid force plate contacts was analyzed for each subject. One gait cycle was defined from the beginning of the stance phase (initial foot-ground contact determined by the vertical ground reaction force) to the end of the subsequent swing phase (immediately before the next foot-ground contact determined by the vertical velocity of the markers on the forefoot).

Data reduction

Pre-processed kinematics and kinetic data (C3D format) were imported to Visual 3D (3.390.23, C-Motion Inc., USA). Kinematic and force data were filtered through a fourth-order Butterworth digital filter at cut-off frequencies of 17 and 55 Hz (32, 34), respectively. Anatomical landmarks and segments were defined according to the Visual 3D framework model and the anthropometric data. The whole body center of mass was determined using a fourteen-segment model (6). The average horizontal velocity of the body center of mass during the whole stride cycle was used to represent the running speed. From the collected three-dimensional data, two-dimensional sagittal plane coordinates were extracted. Data from the right lower extremity were used for the following analyses. Stance phase was defined from the right foot touchdown to toe-off as measured by the force platform, whereas swing phase was defined as from toe off to touchdown of the same foot.

Intersegmental dynamics analysis

The intersegmental dynamics analysis was conducted with a customized program using the data from Visual 3D. The lower limb was modeled as a linked-segment system (thigh, shank, foot) with frictionless joints at the hip, knee, and ankle (8, 15). The origin of the local coordinate system \((x_0, y_0)\) for the system was fixed at hip joint and therefore the motion of the lower limb could be described by \(x_0, y_0\) and segment angles \(\theta_f, \theta_s, \theta_t\) (Fig. 1). The definition of the angular
motion of a segment was positive when the direction of segmental rotation was counterclockwise. Based on free body diagrams of the segments of the lower extremity, the dynamic equations of motion was derived by using the Newton-Euler formula applied to each body segment. The anthropometric inertial parameters for Chinese adults published by Zheng (37) were used to determine the location of the center of mass and the moment of inertia of each body segment. According to earlier research (9, 22, 36), at each of the joints of the linked segments the torque was separated into five categories: net joint (NET), gravitational (GTT), motion-dependent (MDT), contact torque (EXT), and generalized muscle torque (MST). NET is the sum of the other four components:

\[ \text{NET} = \text{GTT} + \text{MDT} + \text{EXT} + \text{MST} \]

Thus NET is the sum of all the positive and negative torque components acting on a joint. MST is the resultant joint torque, mainly generated by muscle contractions. GTT results from gravitational force acting at the centre of each joint. EXT is generated at joints by ground reaction force acting on limb segments. MDT arises from mechanical interactions occurring between limb segments, and is the sum of all motion-dependent torques produced by segment movements (e.g. segment angular velocity and angular acceleration).

To calculate MST at each joint:

\[ \text{MST} = \text{NET} - \text{GTT} - \text{MDT} - \text{EXT} \]

The equations for each component are as follows:

**Ankle torque components:**

\[ \text{NET} = (I_f + m_f r_f^2) \alpha_f \]

\[ \text{MDT (5 subcomponents)} = \text{HLAT} + \text{TAAT} + \text{TAVT} + \text{SAAT} + \text{SAVT} \]

1. due to the hip linear acceleration (HLAT) = \( m_f r_f \left[ a_y \cos(\theta_f) - a_x \sin(\theta_f) \right] \)
2. due to the thigh angular acceleration\( (TAAT) = -m_tr\alpha_t \cos(\theta_f - \theta_t) \)

3. due to the thigh angular velocity\( (TAVT) = -m_tr\omega_t^2 \sin(\theta_f - \theta_t) \)

4. due to the shank angular acceleration\( (SAAT) = -m_tr\alpha_s \cos(\theta_f - \theta_s) \)

5. due to the shank angular velocity\( (SAVT) = -m_tr\omega_s^2 \sin(\theta_f - \theta_s) \)

\[ \text{GTT} = m_trfg \cos(\theta_f) \]

\[ \text{EXT} = F_x[r_f \sin(\theta_f) + d_y] - F_y[r_f \cos(\theta_f) + d_x] \]

### Knee torque components:

\[ \text{NET} = (I_s + m_s \omega_s^2)\alpha_s \]

\[ \text{MDT (7 subcomponents)} = \text{HLAT} + \text{TAAT} + \text{TAVT} + \text{SAAT} + \text{SAVT} + \text{FAAT} + \text{FAVT} \]

1. \[ \text{HLAT} = m_tr_l[\alpha_y \cos(\theta_f) - \alpha_x \sin(\theta_f)] + (m_l_s + m_r_s) [\alpha_y \cos(\theta_s) - \alpha_x \sin(\theta_s)] \]

2. \[ \text{TAAT} = -m_tr\alpha_t \cos(\theta_f - \theta_t) - (m_l_s l_t + m_r_s l_t) \alpha_t \cos(\theta_s - \theta_t) \]

3. \[ \text{TAVT} = -m_tr\omega_t^2 \sin(\theta_f - \theta_t) - (m_l_s l_t + m_r_s l_t) \omega_t^2 \sin(\theta_s - \theta_t) \]

4. \[ \text{SAAT} = -m_tr\alpha_s \cos(\theta_f - \theta_s) - m_l_s^2 \alpha_s \]

5. \[ \text{SAVT} = -m_tr\omega_s^2 \sin(\theta_f - \theta_s) \]

6. due to the foot angular acceleration\( (FAAT) = -(l_f + m_f l_f^2)\alpha_f - m_tr\omega_f \cos(\theta_f - \theta_s) \)

7. due to the foot angular velocity\( (FAVT) = m_tr\omega_f^2 \sin(\theta_f - \theta_s) \)

\[ \text{GTT} = m_trfg \cos(\theta_f) + (m_l_s + m_r_s)g \cos(\theta_s) \]

\[ \text{EXT} = F_x[r_f \sin(\theta_f) + d_y] - F_y[r_f \cos(\theta_f) + d_x] + l_s[F_x \sin(\theta_s) - F_y \cos(\theta_s)] \]

### Hip torque components:

\[ \text{NET} = (I_t + m_t \omega_t^2)\alpha_t \]

\[ \text{MDT (7 subcomponents)} = \text{HLAT} + \text{TAAT} + \text{TAVT} + \text{SAAT} + \text{SAVT} + \text{FAAT} + \text{FAVT} \]

1. \[ \text{HLAT} = m_tr_f [\alpha_y \cos(\theta_f) - \alpha_x \sin(\theta_f)] + (m_l_s + m_r_s) [\alpha_y \cos(\theta_s) - \alpha_x \sin(\theta_s)] + \]
\[(m_f l_f + m_s l_s + m_t l_t) \left[ a_y \cos(\theta_f) - a_x \sin(\theta_f) \right]\]

2. \[TAAT = -m_f l_f \alpha_f \cos(\theta_f - \theta_t) - (m_f l_f l_t + m_s r_s l_t) \alpha_t \cos(\theta_s - \theta_t) - (m_f l_f^2 + m_s l_s^2) \alpha_t\]

3. \[TAVT = -m_f r_f l_f \omega_f^2 \sin(\theta_f - \theta_t) - (m_f l_f l_t + m_s r_s l_t) \omega_t^2 \sin(\theta_s - \theta_t)\]

4. \[SAAT = -(I_s + m_f l_s^2 + m_s r_s^2) \alpha_s - m_f r_f l_f \alpha_f \cos(\theta_f - \theta_t) - (m_f l_s l_t + m_s r_s l_t) \alpha_s \cos(\theta_s - \theta_t)\]

5. \[SAVT = -m_f r_f l_f \omega_f^2 \sin(\theta_f - \theta_s) + (m_f l_s l_t + m_s r_s l_t) \omega_t^2 \sin(\theta_s - \theta_t)\]

6. \[FAAT = -(I_f + m_f r_f^2) \alpha_f - m_f r_f l_f \alpha_f \cos(\theta_f - \theta_s) - m_f r_f l_f \alpha_f \cos(\theta_f - \theta_t)\]

7. \[FAVT = m_f r_f l_f \omega_f^2 \sin(\theta_f - \theta_s) + m_f r_f l_f \omega_f^2 \sin(\theta_f - \theta_t)\]

\[GT = m_f r_f g \cos(\theta_f) + (m_f l_s + m_s r_s) g \cos(\theta_s) + (m_f l_t + m_s l_t + m_t r_t) g \cos(\theta_t)\]

\[EXT = F_x [r_f \sin(\theta_f) + d_y] - F_y [r_f \cos(\theta_f) + d_x] + l_s [F_x \sin(\theta_s) - F_y \cos(\theta_s)] + l_t [F_x \sin(\theta_t) - F_y \cos(\theta_t)]\]

**Nomenclature**

- \(m_f, m_s, m_t\) mass of the foot, shank, and thigh
- \(I_f, I_s, I_t\) moment of inertia about the centre of mass of the foot, shank, and thigh
- \(\theta_f, \theta_s, \theta_t\) segment angles for the foot, shank, and thigh, measured at the distal joint (orientation angle)
- \(\omega_f, \omega_s, \omega_t\) angular velocities of the foot, shank, and thigh
- \(\alpha_f, \alpha_s, \alpha_t\) angular accelerations of the foot, shank, and thigh
- \(r_f, r_s, r_t\) distances from the proximal joint to the centre of mass of the foot, shank, and thigh
- \(l_s, l_t\) lengths of the shank and thigh segments
F_x, F_y  X and Y components of the ground reaction force (GRF)

a_x, a_y  X and Y components of the linear acceleration of the hip joint (x_0, y_0)

d_x, d_y  X and Y distances from the centre of pressure to the centre of mass of the foot

(i.e. x_{cmf} – x_{cop} and y_{cmf} – y_{cop}, respectively, where x_{cmf}, y_{cmf} are the X and Y
co-ordinates of the centre of mass of the foot, and x_{cop}, y_{cop} are the X and Y
co-ordinates of the center-of-pressure)

g  gravitational constant

**Results**

The subjects' average maximal isometric contraction torque of knee flexors was 164.8 ± 29.6 Nm, measured via the isokinetic dynamometer. The average sprinting speed for the 8 subjects was 9.7 ± 0.3 m/s. Figure 2a shows the ensemble curves for knee and hip joint torque during stance phase. MST and EXT were the two main torques counterbalancing each other during stance phase while the other torques (GTT, MDT, NET) were much smaller.

Note that the knee flexion MST and the hip extension MST both reached peak values during the initial stance phase (about 5% of stance phase) (Fig. 2a). These peak values could be easily removed in the normalization and data smoothing process. To show the real situation, the mean ± SD peak values among subjects are presented (Table 1). Figure 2(b) shows the skeleton diagram of the subjects’ sprinting during the initial stance phase. Note that the ground reaction force passed anteriorly to the knee and hip at this moment, which would generate an extension torque at the knee and a flexion torque at the hip joint. Although hip extension MST has larger values later, the knee MST tended to be extension.
As shown in Figure 3(a), both MST and MDT were much greater than the others during the swing phase. They were counterbalancing and reached the maximum at both knee and hip joints at a time point approximately 80% of the way through swing phase. The skeleton diagram during late swing phase is shown in Figure 3(b) and the mean peak values at this moment are shown in Table 2.

Figure 4 shows the ensemble curves of components of motion-dependent torque (MDT) at the hip joint and the knee joint during swing phase. MDT at the hip joint was mainly constituted of the torque due to shank angular acceleration (SAAT), thigh angular acceleration (TAAT), and hip linear acceleration (HLAT). MDT at the knee joint was mainly constituted of the torque due to shank angular acceleration (SAAT) during the entire swing phase.

Discussion

During initial stance phase, the GRF passed in front of the knee and hip joints which resulted in a large extension torque at the knee and a flexion torque at the hip (EXT) (Fig. 2b). These EXT acted at both knee and hip joints, applying stress to the hamstring muscles. To counteract this effect of GRF, the knee flexors and the hip extensors, hamstring muscles served both roles, were required to produce a large flexion torque at knee and an extension torque at hip. This observation is congruent with previous studies (3, 16-18), which showed a large knee flexion MST during initial stance phase, but contradicts from some kinetic findings of no knee flexion torque at this moment (25).

Since these large peak values appeared within a very short period of time, they could easily be removed as a noise spike by using an inappropriate filtering method, which may explain the inconsistent findings in terms of hamstring mechanics during early stance in maximum speed sprinting. In the study of Schache et al. (25), peak stance musculotendon force
for the bi-articular hamstrings would seem to have been underestimated in the early stance phase and the authors ascribed this underestimation to the computational approach used to calculate muscle forces, that is, the limitations of inverse dynamics-based static optimization combined with a minimum-stress performance criterion. However, in our opinion, the cause of this underestimation could be that erroneously low (or zero) knee flexion torque and hip extension torque were taken to calculate individual muscle forces. Compared with their previous results which also demonstrated a knee flexion MST during initial stance phase (24), some peak values of joint moments might be removed artificially (25).

The average peak MST at knee and hip joints were -203.4 ±93.6 Nm and 455.2 ±198.7 Nm, respectively, during initial stance phase (Table 1). Based on the MRI and videofluoroscopy results (2, 10, 26), the 2D moment arm of the hamstrings at the knee joint in the sagittal plane was approximately 0.02 m - 0.04 m. We could reasonably estimate the peak hamstring force across the knee joint based on the MST values at knee, and it ranged from 5777 - 11554 N, which is at least 8 times of the subjects' average body weight. Furthermore, since the subjects' maximal isometric contraction force of the knee flexors ranged from 4120 - 8241 N (estimated from the results measured via the isokinetic dynamometer, 164.8 ± 29.6 Nm), the knee flexor force during the initial stance phase was 40% larger than that produced by the maximal isometric knee flexion. Clearly a huge load acts on the hamstrings during sprinting.

In addition, the MST is a net effect of both agonist and antagonist activities. Thus, the hamstrings encounter the knee extensors (quadriceps femoris) to generate this flexor torque, which means the actual knee extension torques that need to be generated by hamstrings might be even greater than the present results. In this case, there would be a high strain injury risk during the initial stance phase due to the sprinter's hamstring strength deficits.
During late swing phase, the thigh started to extend backward but the shank still rotated forward due to MDT. In order to pull the shank backward and downward before ground contact, the hamstring muscles are intensely contracted creating an (clockwise) acceleration where there is a rapid change from eccentric to concentric function (Fig. 3b). Our data revealed that the largest muscle torque (MST) occurred at the end of the swing phase (Figure 3a), where the largest hip extension and knee flexion MST happened at almost the same time, and the MST was used mainly to counterbalance the MDT during swing phase. The mean ± SD peak values of MST at knee and hip joint were -249.3 ± 38.8 Nm and 650.8 ± 101.1 Nm (Table 2) respectively. Using the force arm of the hamstring muscles based on MRI studies, we could also estimate that the force produced by the knee flexors at this moment. It was from 6225 - 12450 N, which is approximately 10 times of the subjects' average body weight and 50% larger than that generated during the maximal isometric knee flexion.

As with the loading conditions during initial stance phase, it was necessary to take the antagonist activities into consideration. Thus the actual torques produced by the hamstring muscles at the knee and hip might be greater than those we estimated. The hamstrings loading condition was maximized during this phase as well. This was consistent with most of the previous studies (23, 24, 28, 30, 35) which reported that the peak hamstring stretch and force occur during late swing phase of sprinting before foot contact. In addition, our results highlighted that this high load on the hamstrings was caused by the MDT, since the MST functioned as to counterbalance the MDT to control the rapid limb rotation during the swing phase. We further found that the major component of MDT at both knee and hip was the motion-dependent torque due to the acceleration of shank (Fig. 4). These findings may answer the question of why the
hamstrings were stretched to their maximum length and the muscle force reached its maximal value during the later swing phase according to the observations of other researchers.

In summary, our analysis of MST via intersegment dynamics indicated that the hamstring muscles experience tremendous loads in both initial stance phase and late swing phase. This is in consistent with the previous EMG studies (5, 35), reporting that peak activities of the medial and lateral hamstrings occurred during the initial stance and late swing. Although force load on its own is not a strong predictor of injury, the results suggest there would be greater strain risk during these two phases. Furthermore, our analyses revealed the reasons behind those high loading conditions, that is, EXT (by GRF) in the initial stance phase and MDT (mainly by shank angular acceleration) in the late swing phase, respectively. The values of flexion torque at the knee and extension torque at the hip in those two phases were considerable, indicating that the knee flexors and hip extensors play a very important role in sprint running, especially during initial stance phase and later swing phase. These findings may help inform coaches and athletes in designing appropriate training protocols and injury prevention strategies that focus on emphasizing knee flexors and hip extensors on the basis of the characteristics of MST.

Our previous work (13) showed all of the major muscles that cross the hip and knee joint were activated above minimum level during running, including mono-articular (gluteus maximus, vastus lateralis, biceps femoris short head) and bi-articular (rectus femoris, hamstrings, and gastrocnemius) muscles. In addition, passive structures also contribute to joint torques at both the joints. However, hamstrings are the only bi-articular muscles that flex knee and extend hip, in addition to the fact that hamstrings are the most injured muscles during sprint (14, 33). Therefore, we have focused our MST related discussions on the hamstring. Future studies need to consider the role of other active and passive structures that cross the hip and knee joints. Their
contributions to the hip joint extension and knee joint flexion torque, and their influence on the
dynamics of the hamstrings, need to be further studied. Moreover, some recent research indicates
that during inverse dynamics analysis of locomotion, mismatched cut-off frequencies applied to
the kinematic and kinetic data will likely affect the calculated joint torques (1, 11). This might be
a potential limitation of this study and should be treated with caution in further research.

During initial stance phase and late swing phase, the passive torques (EXT & MDT
produced by GRF and the inertial movement of the segments of the lower extremity) applied
stress to the hamstring muscles in opposite directions at both knee and hip joints. To counter
these large passive effects, the hamstring muscles endure high mechanical loads which may lead
to strains. By understanding the loading condition on hamstring muscles, especially the load
production mechanism, injury prevention programs and rehabilitation approaches can be
developed to mitigate the high risk of hamstring strain injuries during high speed running.

Acknowledgments

Figure Captions

Figure 1. Model of lower limb. \( \theta_f, \theta_s, \theta_t \): segment angles for the foot, shank, and thigh, measured at the distal joint; \( x_0, y_0 \): the X and Y coordinates of the hip; \( x_{cop}, y_{cop} \): the X and Y coordinates of the center-of-pressure).

Figure 2. (a) Averaged time-normalized graphs for joint torques at the knee and hip joints during stance phase. The top panel shows positions of the lower extremity during stance phase. Data represents the group mean (lines) with one SD (shading). (b) Diagram of sprinting during the initial stance phase, the ground reaction force passes anteriorly to the knee and hip joints. (NET: Net joint torque; MST: Muscle torque; GTT: Gravitational torque; EXT: Contact Torque; MDT: Motion-dependent Torque. +: extension, -: flexion).

Figure 3. (a) Averaged time-normalized graphs for joint torques at knee and hip joints during swing phase. The top panel shows positions of the lower extremity during swing phase. Data represents the group mean (lines) with one SD (shading). (b) Diagram of sprinting during the late swing phase, the inertial loads produced by segment motion work at the knee and hip joints. (NET: Net joint torque; MST: Muscle torque; GTT: Gravitational torque; MDT: Motion-dependent Torque. +: extension; -: flexion).

Figure 4. Ensemble curves of subcomponents of motion-dependent torques at the hip (a) and knee (b) joints during swing phase (FAAT: Torque due to foot angular acceleration; FAVT: Torque due to foot angular velocity; HLAT: Torque due to hip linear acceleration; SAAT: Torque due to shank angular acceleration; SAVT: Torque due to shank angular velocity; TAAT: Torque due to thigh angular acceleration; TAVT: Torque due to thigh angular velocity; +: extension torque, -: flexion torque).
Figure 1
Figure 2

(a) Graph showing knee and hip joint torques as a function of stance phase. The graph includes lines for EXT, GTT, MDT, MBT, and NET.

(b) Diagram illustrating the direction of stretching.

The direction of stretching is shown with an arrow labeled EXT and GRF.
Figure 3

(a) Graph showing knee and hip joint torques in relation to swing phase.

(b) Diagram illustrating the direction of stretching during the swing phase.

Key:
- GTT
- MDT
- MST
- NET
Figure 4

(a) Subcomponents of MDT [Nm] for the hip joint.

(b) Subcomponents of MDT [Nm] for the knee joint.

Swing phase [%]
Table 1: Maximum MST, EXT at the knee and hip joint, maximum GRF during initial stance phase.

| Joint | MST (Nm)       | EXT (Nm)   | GRF(N)    |
|------|----------------|------------|-----------|
| Knee | -203.4 ± 93.6  | 96.8 ± 76.1| 1037.9 ± 350.3 |
| Hip  | 455.2 ± 198.7  | -218.6 ± 131.0 |         |

Values are mean ± SD. MST: Muscle torque; EXT: Contact Torque; GRF: Ground reaction force. (+: extension; -: flexion)
Table 2: Maximum MST, MDT at the knee and hip joint during late swing phase.

| Joint | MST (Nm)       | MDT (Nm)       |
|-------|----------------|----------------|
| Knee  | -249.3 ± 38.8  | 191.1 ± 35.6   |
| Hip   | 650.8 ± 101.1  | -406.7 ± 89.6  |

Values are mean ± SD. MST: Muscle torque; MDT: Motion-dependent Torque. (+: extension; -: flexion)
