Abstract

A new training algorithm is presented for delayed reinforcement learning problems that does not assume the existence of a critic model and employs the polytope optimization algorithm to adjust the weights of the action network so that a simple direct measure of the training performance is maximized. Experimental results from the application of the method to the pole balancing problem indicate improved training performance compared with critic-based and genetic reinforcement approaches.

Keywords: reinforcement learning, neurocontrol, optimization, polytope algorithm, pole balancing, genetic reinforcement.
TRAINING REINFORCEMENT NEUROCONTROLLERS USING THE POLYTOPE ALGORITHM

Abstract

A new training algorithm is presented for delayed reinforcement learning problems that does not assume the existence of a critic model and employs the polytope optimization algorithm to adjust the weights of the action network so that a simple direct measure of the training performance is maximized. Experimental results from the application of the method to the pole balancing problem indicate improved training performance compared with critic-based and genetic reinforcement approaches.

Keywords: reinforcement learning, neurocontrol, optimization, polytope algorithm, pole balancing, genetic reinforcement.

1 Introduction

In the framework of delayed reinforcement learning, a system receives input from its environment, decides for a proper sequence of actions, executes them, and thereafter receives a reinforcement signal, namely a grade for the made decision. A system at any instant is described by its, so called, state variables. The objective of a broad class of reinforcement problems, is to learn how to control a system in such a way, so that its state variables remain at all times within prescribed ranges. However, if at any instant, the system violates this requirement, it is penalized by receiving a "bad grade" signal, and hence its policy in making further decisions is influenced accordingly.

There are many examples of this kind of problems, like the pole balancing problem, teaching an autonomous robot to avoid obstacles, the ball and beam problem etc.

In general we can distinguish two kinds of approaches that have been developed for delayed reinforcement problems: the critic-based approaches and the direct approaches. There is also the Q-learning approach which exhibits many similarities with the critic-based ones. The most well-studied critic-based approach is the Adaptive Heuristic Critic (AHC) method which assumes two separate models: an action model that receives the current system state and selects the action to be taken and the evaluation model which provides as output a prediction $e(x)$ of the evaluation of the current state $x$. The evaluation model
is usually a feedforward neural network trained using the method of temporal
differences, i.e. it tries to minimize the error \( \delta = e(x) - (r + \gamma e(y)) \) where \( y \) is the new state, \( r \) the received reinforcement and \( \gamma \) a discount factor [3, 1, 2]. The action model is also a feedforward network that provides as output a vector of probabilities upon which the action selection is based. Both networks are trained on-line through backpropagation using the same error value \( \delta \) described previously.

The direct approach to delayed reinforcement learning problems considers reinforcement learning as a general optimization problem with an objective function having a straightforward formulation but which is difficult to optimize [4]. In such a case only the action model is necessary to provide the action policy and optimization techniques must be employed to adjust the parameters of the action model so that a stochastic integer-valued function is maximized. This function is actually proportional to the number of successful decisions (i.e. actions that do not lead to the receipt of penalty signal). A previous direct approach to delayed reinforcement problems employs real-valued genetic algorithms to perform the optimization task [10]. In the present study we propose another optimization strategy that is based on the polytope method with random restarts. Details concerning such an approach are presented in the next section, while section 3 provides experimental results from the application of the proposed method to the pole balancing problem and compares its performance against that of the AHC method and of the evolutionary approach.

## 2 The Proposed Training Algorithm

As already mentioned, the proposed method belongs to the category of direct approaches to delayed reinforcement problems. Therefore, only an action model is considered that in our case has the architecture of a multilayer perceptron with input units accepting the system state at each time instant, and sigmoid output units providing output values \( p_i \) in the range \((0, 1)\). The decision for the action to be taken from the values of \( p_i \) can be made either stochastically or deterministically. For example in the case of one output unit the value \( p \) may represent the probability that the final output will be one or zero, or the final output may be obtained deterministically using the rule: if \( p > 0.5 \) the final output will be one, otherwise it will be zero. Learning proceeds in cycles, with
each cycle starting with the system placed at a random initial position and ending with a failure signal. Since our objective is to train the network so that the system ideally never receives a failure signal, the number of time steps of the cycle (i.e. its length), constitutes the performance measure to be optimized. Consequently, the training problem can be considered as a function optimization problem with the adjustable parameters being the weights and biases of the action network and with the function value being the length of a cycle obtained using the current weight values. In practice, when the length of a cycle exceeds a preset maximum number of steps, we consider that the controller has been adequately trained. This is used as a criterion for terminating the training process. The training also terminates if the number of unsuccessful cycles (i.e. function evaluations without reaching maximum value) exceed a preset upper bound.

Obviously, the function to be optimized is integer-valued, thus it is not possible to define derivatives. Therefore, traditional gradient-based optimization techniques cannot be employed. Moreover, the function possesses an amount of random noise since the initial state specification as well as the action selection at the early steps are performed at random. On one hand the incorporation of this random noise may disrupt the optimization process. For example, if the evaluation of the same network is radically different at different times, then the learning process will be misled. On the other hand, the global search certainly benefits from it and hence the noise should be kept, however under control.

It is clear that the direct approach has certain advantages which we summarize in the following list.

- Instead of using an on-line update strategy for the action network, we perform updates only at the end of each cycle. Therefore, the policy of the action network is not affected in the midst of a cycle (during which the network actually performs well). The continuous on-line adjustment of the weights of the action network may lead due to overfitting, to the corruption of correct policies that the system has acquired so far [10].

- Several sophisticated, derivative-free, multidimensional optimization techniques may be employed instead of the naive stochastic gradient descent.

- Stochastic action selection is not necessary (except only at the early steps of each cycle). In fact stochastic action selection may cause problems, since
it may lead to choices that are not suggested by the current policy \[10\].

- There is no need for a critic. The absence of a critic and the small number of weight updates contribute to the increase of the training speed.

The main disadvantage of the direct approach is that its performance relies mainly on the effectiveness of the used optimization strategy. Due to the characteristics of the function to be optimized one cannot be certain that any kind of optimization approach will be suitable for training.

As already stated, a previous reinforcement learning approach that follows a direct strategy, employs optimization techniques based on genetic algorithms and provides very good results in terms of training speed (required number of cycles) \[16\]. In this work, we present a different optimization strategy based on the polytope algorithm \[12, 8, 13\], which is described next.

2.1 The Polytope Algorithm

The Polytope algorithm belongs to the class of direct search methods for non-linear optimization. It is also known by the name Simplex, however it should not be confused with the well known Simplex method of linear programming. Originally this algorithm was designed by Spendley et al. \[14\] and was refined later by Nelder and Mead \[12\]. A polytope (or simplex) in $\mathbb{R}^n$ is a construct with $(n+1)$ vertices (points in $\mathbb{R}^n$) defining a volume element. For instance in two dimensions the simplex is a triangle, in three dimensions it is a tetrahydron, and so on so forth. In our case each vertex point $w_i = (w_{i1}, \ldots, w_{in})$ describes the $n$ parameters (weights and thresholds) of an action network.

The input to the algorithm apart from a few parameters of minor importance, is an initial simplex, ie $(n+1)$ points $w_i$. The algorithm brings the simplex in the area of a minimum, adapts it to the local geometry, and finally shrinks it around the minimizer. It is a derivative-free, iterative method and proceeds towards the minimum by manipulating a population of $n+1$ points (the simplex vertices) and hence it is expected to be tolerant to noise, inspite its deterministic nature. The steps taken in each iteration are described below. (We denote by $f$ the objective function and by $w_i$ the simplex vertices).

1. Examine the termination criteria to decide whether to stop or not.
2. Number the simplex vertices $w_i$, so that the sequence $f_i = f(w_i)$ is sorted in ascending order.

3. Calculate the centroid of the first $n$ vertices: \( c = \frac{1}{n} \sum_{i=0}^{n-1} w_i \)

4. Invert the "worst" vertex $w_n$ as: \( r = c + \alpha(c - w_n) \) (usually $\alpha = 1$)

5. If $f_0 \leq f(r) \leq f_{n-1}$ then
   set $w_n = r$, $f_n = f(r)$, and go to step 1
   endif

6. If $f(r) < f_0$ then
   Expand as: \( e = c + \gamma(r - c) \) ($\gamma > 1$, usually $\gamma = 2$)
   If $f(e) < f(r)$ then
     set $w_n = e$, $f_n = f(e)$
   else
     set $w_n = r$, $f_n = f(r)$
   endif
   go to step 1
   endif

7. If $f(r) \geq f_{n-1}$ then
   If $f(r) \geq f_n$ then
     contract as: \( k = c + \beta(w_n - c) \), ($\beta < 1$, usually $\beta = \frac{1}{2}$)
   else
     contract as: \( k = c + \beta(r - c) \)
   endif
   If $f(k) < \min(f(r), f_n)$, then
     set $w_n = k$, $f_n = f(k)$
   else
     Shrink the whole polytope as:
     Set $w_i = \frac{1}{2}(w_0 + w_i)$, $f_i = f(w_i)$ for $i = 1, 2, \ldots, n$
   endif
   go to step 1
   endif

In essence the polytope algorithm considers at each step a population of $(n+1)$ action networks whose weight vectors $w_i$ are properly adjusted in order to obtain
an action network with high evaluation. In this sense, the polytope algorithm, although developed earlier, exhibits an analogy with genetic algorithms which are also based on the recombination of a population of points.

The initial simplex may be constructed in various ways. The approach we followed was to pick the first vertex at random. The rest of the vertices were obtained by line searches originating at the first vertex, along each of the $n$ directions. This initialization scheme proved to be very effective for the pole balancing. Other schemes such as, random initial vertices or constrained random vertices on predefined directions, etc, did not work well. The termination criterion relies on comparing a measure for the polytope’s ”error” to a user preset small positive number. Specifically the algorithm returns if:

$$\frac{1}{n+1} \sum_{i=0}^{n} |f_i - \bar{f}| \leq \epsilon$$

where $\bar{f} = \frac{1}{n+1} \sum_{i=0}^{n} f_i$.

The use of the polytope algorithm has certain advantages like robustness in the presence of noise, simple implementation and derivative-free operation. These characteristics make this algorithm a suitable candidate for use as an optimization tool in a direct reinforcement learning scheme. Moreover, since the method is deterministic, its effectiveness depends partly on the initial weight values. For this reason, our training strategy employs the polytope algorithm with random restarts as it will become clear in the application presented in the next section.

It must also be stressed that the proposed technique does not make any assumption concerning the architecture of the action network, (which in the case described here is a multilayer perceptron), and can be used with any kind of parameterized action model (e.g. the fuzzy-neural action model employed in the GARIC architecture [4]).

3 Application to the Pole Balancing Problem

The pole balancing problem constitutes the best-studied reinforcement learning application. It consists of a single pole hinged on a cart that may move left or right on a horizontal track of finite length. The pole has only one degree of freedom (rotation about the hinge point). The control objective is to push the cart either left or right with a force so that the pole remains balanced and the cart is kept within the track limits.

Four state variables are used to describe the status of the system at each time instant: the horizontal position of the cart ($x$), the cart velocity ($\dot{x}$), the angle of
the pole ($\theta$) and the angular velocity ($\dot{\theta}$). At each step the action network must decide the direction and magnitude of force $F$ to be exerted to the cart. Details concerning the equations of motion of the cart-pole system can be found in [2, 16, 11]. Through Euler’s approximation method we can simulate the cart-pole system using discrete-time equations with time step $\Delta \tau = 0.02$ sec. We assume that the system’s equations of motion are not known to the controller, which perceives only the state vector at each time step. Moreover, we assume that a failure occurs when $|\theta| > 12$ degrees or $|x| > 2.4m$ and that training has been successfully completed if the pole remains balanced for more than 120000 consecutive time steps. Two versions of the problem exist concerning the magnitude of the applied force $F$. We are concerned with the case where the magnitude is fixed and the controller must decide only the direction of the force at each time step. Obviously the control problem is more difficult compared to the case where any value for the magnitude is allowed. Therefore, comparisons will be presented only with fixed magnitude approaches and we will not consider architectures like the RFALCON [11], which are very efficient but assume continuous values for the force magnitude.

The polytope method is embedded in the MERLIN package [6, 7] for multi-dimensional optimization. Other derivative-free methods, provided by MERLIN have been tested in the pole-balancing example (random, roll [6]), but the results were not satisfactory. On the contrary, the polytope algorithm was very effective being able to balance the pole in a relative few number of cycles (function evaluations) which was less than 1000 in many cases. As mentioned in the previous section, the polytope method is deterministic, thus its effectiveness depends partly on the initial weight values. For this reason we have employed an optimization strategy that is based on the polytope algorithm with random restarts. Each run starts by randomly specifying an initial point in the weight space and constructing the initial polytope by performing line minimizations along each of the $n$ directions. Next, the polytope algorithm is run for up to 100 function evaluations (cycles) and the optimization progress is monitored. If a cycle has been found lasting more than 100 steps, application of the polytope algorithm continues for additional 750 cycles, otherwise we consider that the initial polytope was not proper and a random restart takes place. A random restart is also performed when after the additional 750 function evaluations the algorithm has not converged, i.e., a cycle has not been encountered lasting for more than 120000 steps.
Table 1: Training performance in terms of required number of training cycles

| Method | Best    | Worst | Mean  | SD    |
|--------|---------|-------|-------|-------|
| Polytope | 217     | 10453 | 2250  | 1955  |
| AHC    | 4123    | 12895 | 6175  | 2284  |
| GA-100 | 886     | 11481 | 4097  | 2205  |

(this maximum value is suggested in [1, 16]). In the experiments presented in this article a maximum of 15 restarts was allowed. The strategy was considered unsuccessfully terminated if 15 unsuccessful restarts were performed or the total number of function evaluations was greater than 15000.

The above strategy was implemented using the MCL programming language [5] that is part of the MERLIN optimization environment. The initial weight values at each restart were randomly selected in the range $(-0.5, 0.5)$. Experiments were also conducted that considered the ranges $(-1.0, 1.0)$ and $(-2.0, 2.0)$ and the obtained results were similar, showing that the method exhibits robustness as far as the initial weights are concerned.

For comparison purposes the action network had also the same architecture with the architecture reported in [16, 2]. It is a multilayer perceptron with four input units (accepting the system state), one hidden layer with five sigmoid units and one sigmoid unit in the output layer. There are also direct connections from the input units to the output unit. The specification of the applied force characteristics from the output value $y \in (0, 1)$ was performed in the following way. At the first ten steps of each cycle the specification was probabilistic, i.e. $F = 10N$ with probability equal to $y$. At the remaining steps the specification was deterministic, i.e., if $y > 0.5$ then $F = 10N$, otherwise $F = -10N$. In this way, a degree of randomness is introduced in the function evaluation process that assists in escaping from plateaus and shallow local minima.

Experiments have been conducted to assess the performance of the proposed training method both in terms of training speed and generalization capabilities. For comparison purposes we have also implemented the AHC approach [1, 2], while experimental results concerning the genetic reinforcement approach on the same problem using the same motion equations and the same network architecture
Table 2: Generalization performance in terms of the percentage of successful tests.

| Method  | Best | Worst | Mean | SD  |
|---------|------|-------|------|-----|
| Polytope| 88.1 | 2.3   | 47.2 | 16.4|
| AHC     | 62.2 | 9.5   | 38.5 | 10.3|
| GA-100  | 71.4 | 3.9   | 47.5 | 14.2|

are reported in [16]. Training speed is measured in terms of the number of cycles (function evaluations) required to achieve a successful cycle. A series of 50 experiments were conducted using each method, with each cycle starting with random initial state variables. Obtained results are summarized in Table 1, along with results from [16] concerning the genetic reinforcement case with population of 100 networks (GA-100) that exhibited the best generalization performance. In accordance with previous published results, the AHC method does not manage to find a solution in 14 of the 50 experiments (28%), so the displayed results concern values obtained considering only the successful experiments. On the contrary, the proposed training strategy was successful in all the experiments and exhibited significantly better performance with respect to the AHC case in terms of the required training cycles. From the displayed results it is also clear that the polytope method outperforms the genetic approach, which is also better than the AHC method.

Moreover, we have tested the generalization performance of the obtained action networks. These experiments are useful since a successful cycle starting from an arbitrary initial position, does not necessarily imply that the system will exhibit acceptable performance when started with different initial state vectors. The generalization experiments were conducted following the guidelines suggested in [16]: for each action network obtained in each of the 50 experiments either using the polytope method or using the AHC method, a series of 5000 tests were performed from random initial states and we counted the percentage of the tests in which the network was able to balance the pole for more than 1000 time steps. The same failure criteria that were used for training were also used for testing. Table 2 displays average results obtained by testing the action networks obtained using the polytope and the AHC method (in the case of successful training exper-
iments). Moreover, it provides generalization results provided in [10] concerning the GA-100 algorithm, using the same testing criteria. As the results indicate the action networks obtained by all methods exhibit comparative generalization performance. As noted in [10] it is possible to increase the generalization performance by considering stricter stopping criteria for the training algorithm. It must also be noted that, in what concerns the polytope method, there was not any connection between training time and generalization performance, i.e., the networks that resulted by longer training times did not necessarily exhibit better generalization capabilities.

From the above results it is clear that direct approaches to delayed reinforcement learning problems constitute a serious alternative to the most-studied critic-based approaches. While critic-based approaches are mainly based on their elegant formulation based on temporal differences and stochastic dynamic programming, direct approaches base their success on the power of the optimization schemes they employ. Such an optimization scheme based on the polytope algorithm with random restarts has been presented in this work and was proved to be very successful in dealing with the pole balancing problem. Future work will be focused on the employment of different kinds of action models (for example RBF networks) as well as the exploration of other derivative-free optimization schemes.
