ABSTRACT: In this paper, we propose a concrete teleportation protocol in the SYK model based on a particle traversing a wormhole. The required operations for the communication, and insertion and extraction of the qubit, are all simple operators in terms of the basic qubits. We determine the effectiveness of this protocol, and find a version achieves almost perfect fidelity. Many features of semiclassical traversable wormholes are manifested in this setup.
1 Introduction

Recent constructions of traversable wormholes [1, 2] provide a causal probe of the ER=EPR [3] relation between entanglement and geometry. A pair of black holes in thermofield double state have their interiors connected via a Einstein-Rosen bridge behind the horizon. The Einstein-Rosen bridge is non-traversable so signals cannot get through the wormhole although the black hole interiors are spatially connected. The basic mechanism found in
[1] is that the gravitational backreaction to quantum effects induced by generic couplings between the exterior regions of the pair of black holes can render the wormhole traversable. One of the most interesting consequences is that a region of connected spacetime which would have been cloaked behind the horizon becomes visible to the external boundaries. Many recent works have studied traversable wormholes in more general settings, e.g. [4–8].

It was conjectured by [1, 2] that sending quantum information through such a wormhole is the gravitational description of quantum teleportation in the dual many-body system. Let us denote the two black holes by \( l \) and \( r \), which are initially in the thermofield double state. The physical picture behind this teleportation is quite simple: the qubit that is teleported from \( l \) to \( r \) is carried by a particle that travels through the dual wormhole.

For a qubit thrown into one side of the system at a sufficiently early time, one just needs to wait long enough (of order the scrambling time) so that the qubit is sufficiently mixed with the black hole microstates, then apply a simple coupling between \( l \) and \( r \), and finally wait for another scrambling time for the qubit to appear on the other side.

Many subsequent works developed this picture in more detail. In [9], a scrambling process combined with teleportation protocol was compared with the traversable wormhole protocol. Their protocol requires precursor operators with a much higher complexity than the simple coupling between \( l \) and \( r \). In [10], the traversable wormhole was understood as a quantum channel. In [11], a nontrivial protocol was proposed to decode a qubit that has been highly scrambled in a black hole background. However, not all of the features of the protocol suggested by traversable wormholes are manifested in these versions, particularly that fact that only simple operators are required. Moreover, as we will discuss further below, other effects can lead to teleportation associated to fully scrambled (essentially random unitarity) dynamics, one sign of which is time inversion of the transmitted quantum information.

In this paper, we propose a precise teleportation protocol using \( N \) qubit fermionic systems that correspond to gravity in a nearly AdS\(_2\) black hole spacetime. We will determine the fidelity of teleportation by computing the mutual information between a reference qubit that is initially in a Bell state with the injected qubit on the left and a final register qubit on the right. We find an optimal method for encoding the qubit in terms of the basic fermions that leads to perfect teleportation for large \( N \) in a certain limit on the parameters describing the dynamics of fermionic system. More generally, we also investigate the separability of the final state when the mutual information is sub-maximal, to determine when the information transfer is truly quantum.

We examine this in detail in the SYK model [13, 14] with \( q \)-point random interactions [15], which is solvable in large \( N \) limit. Our protocol involves applying SWAP operations constructed out of simple operators of the SYK model to insert the qubit into the black hole from the left side and extract it on the right side, as well as a communication channel between \( l \) and \( r \) that involves a coupling of only the basic fermions, of the type used in [2, 16] (see Fig. 1). Recent works studying traversable wormholes using the SYK model

---

\(^1\)A very recent work [12] proposed a protocol of teleportation by size of operators, which in that sense is similar to traversable wormholes.
can been found in e.g. [17–23].

One can construct Dirac fermions out of pairs of the basic Majoranas, and the teleported qubits are encoded in those Dirac fermion occupation numbers. It is particularly interesting to examine situations which have a clear dual description in terms of a particle physically propagating through the wormhole. If our qubit was encoded in the occupation number of a bulk fermion mode, then at low temperatures, it would be distinguishable from the thermal atmosphere. Note that at high temperatures, there is a significant probability that a given mode is already occupied in the Hartle-Hawking state itself.

The bulk description of the Majorana SYK model is slightly more complicated at the boundary, and the fundamental fermions have occupation number \( \langle \hat{N} \rangle = \frac{1}{2} \) in the thermal state at any temperature. Nevertheless, the correlation function between the number operators in the left and right systems are small at low temperature, and the desired behavior can still be seen. In particular, after SWAP the qubit into SYK, the occupation number of fundamental fermions will change according to the qubit.

We find the associated solution in the classical large \( N \) limit in terms of the collective bilocal variables \( G \) and \( \Sigma \). To solve the classical equations we further specialize to the large \( q \) limit where they simplify. Even at low temperatures, our analysis goes beyond the leading Schwarzian approximation.

The effect of the instantaneous interaction required for teleportation can be described exactly in terms of its action on the basic Majoranas. This results in a non-trivial transformation of the bilocal field \( G \) that we determine. Thus in the large \( N \) limit, the problem reduces to finding a solution with that twist boundary condition across the moment of interaction.

Features of the full \( G-\Sigma \) solution beyond the Schwarzian mode are important in understanding teleportation. In particular, in the Schwarzian approximation, the leading order \( 1/N \) classical solution for the collective reparametrization field due to the interaction would lead to a pole in the response measured by the occupation number on the right, whereas Fermi statistics demands that this number is bounded by 1. We will find a consistent result from classical \( G-\Sigma \) solution, which allows us to determine the fidelity of the teleportation protocol.

An exact bulk dual of the SYK model is not yet known, but we will often refer to the gravity description for intuition and to interpret our results. At low temperatures in the large \( N \) limit, the correlation functions of fermions in SYK agree with free fields in the two dimensional bulk spacetime, corrected at leading order in \( 1/N \) by exchanges of the Schwarzian soft mode. This approximation, which is equivalent to bulk fermions minimally coupled to Jackiw-Teitelboim gravity, suffices to match the physics of traversable wormholes in the appropriate regime.

On the gravity side, stringy corrections lead to inelastic effects in the out of time order correlators that describe quantum chaos [24, 25], and we will analogously refer to such features in SYK in that way. The \( G-\Sigma \) boundary bi-local variables, however, have not yet been recast in a manner that looks like a bulk string field theory.

We find that many features of semiclassical traversable wormholes are manifested in this setup. In particular, the coupling between \( l \) and \( r \) can be rather general while main-
taining the fidelity of the protocol. Moreover, if we insert a sequence of qubits into the system in an appropriate time window, these qubits will come out with the same time ordering, as indicated by the smooth semiclassical geometry of a traversable wormhole.

This should be contrasted with what occurs in what one might call the fully scrambled regime, when the evolution $e^{iHt}$ is effectively equivalent to a random unitary. Signals can still reach the right, however they appear in reverse time order. We check that with our protocol some quantum information can be sent in this case only at very high temperatures, although the fidelity is submaximal.

At low temperatures in the gravity description, the fully scrambled regime corresponds to a particle sent so early into the black hole that it has a destructive ultra high energy collision with the negative energy squeezed state generated by the interaction protocol and it does not smoothly pass through the wormhole. Nevertheless signals can be detected on the right due to a quantum interference effect \cite{2, 26}. Our protocol involves encoding a qubit into one of the fermions, rather than simple signaling as measured by a left-right causal propagator. It would be interesting to understand if there is a bulk description of the partially successful teleportation we find at very high temperatures in the fully scrambled regime.

We also find another regime in which qubits arrive on the right in inverse time order. This appears at any temperature when the qubit is injected too late. In that case, the traversing trajectory will be very close to ultimate horizon of the traverable wormhole, and it is likely that quantum fluctuations of the geometry, or stringy effects related to the AdS boundary in whatever is the exact dual of the SYK model are important. We leave further exploration of that effect in the bulk description to future work.

An important feature of the traversable wormhole teleportation protocol is that the qubit travels through the deep interior of the spacetime, and thus it is insensitive to single boundary simple unitary operations after the qubit is sufficiently scrambled. Therefore this is teleportation of a highly error protected qubit.

The structure of this paper is as follows. In Sec. 2, we introduce the protocol and describe its detailed realization in the SYK model. To assess the effectiveness of the protocol, we need to calculate various correlation functions, which we do in Sec. 3, in the large $q$ limit. In Sec. 4, we demonstrate the effectiveness of the protocol. In Sec. 5 we discuss four aspects of the protocol: the fully scrambled interference regime, more general choices of coupling, teleportation of multiple qubits, and whether any quantum information is transmitted in cases with submaximal fidelity. We conclude in Sec. 6.

Appendix A contains further details of the solution of the key correlation function.

2 A simple wormhole teleportation protocol

2.1 General setup

Consider 5 systems: $R$, $Q$, $l$, $r$, $T$. Let $R$, $Q$, $T$ be single qubit systems, where $R$ will play the role of a reference, and information will transferred from $Q$ to $T$. Let $l$ and $r$ be two identical systems of $N/2$ qubits, where we will take $N$ to be large.
Figure 1: The protocol via SWAP operators. $U_t = e^{-iHt}$ is the time evolution of SYK system.

We will consider $l$ and $r$ to be physically realized as systems of $N$ Majorana fermions, pairs of which can be identified as Dirac fermions. Taking $l$ and $r$ together there are a total of $N$ qubits. Time evolution will be generated by the SYK model Hamiltonian acting on these fermionic systems, as discussed further in the next section.

A Majorana fermion presentation of a qubit system can be constructed as follows\(^2\)

$$
\psi_{2j-1}^l = \frac{1}{\sqrt{2}}(ZX)^{j-1}XX^{N/2-j}, \quad \psi_{2j}^l = \frac{1}{\sqrt{2}}(ZX)^{j-1}YX^{N/2-j} \quad (2.1)
$$

$$
\psi_{2j-1}^r = \frac{1}{\sqrt{2}}(ZX)^{j-1}IY^{N/2-j}, \quad \psi_{2j}^r = \frac{1}{\sqrt{2}}(ZX)^{j-1}IZ^{N/2-j} \quad (2.2)
$$

where $X,Y,Z,I$ stand for the Pauli matrices and 2 by 2 identity, respectively. In the above notation, each Majorana fermion is tensor product of $N$ 2 by 2 matrices acting on $N$ distinct qubits in which odd numbered qubits are assigned to the $l$ system and even numbered qubits are assigned to the $r$ system. For notational simplicity, we omit all tensor product symbols and powers $A^n$ should be interpreted in the tensor product sense $A \otimes \cdots \otimes A$.

Initially, $RQ$ are in a maximally entangled state

$$
|\phi_0\rangle = \frac{1}{\sqrt{2}}(|00\rangle + |11\rangle) \quad (2.3)
$$

$l$ and $r$ are in the thermofield double state

$$
|\text{tfd}\rangle = \frac{1}{Z} \sum_n e^{-\beta E_n/2} |nn\rangle_{lr} \quad (2.4)
$$

and $T$ is in the state $|0\rangle$. Success of teleportation from $Q$ to $T$ using the entanglement resource of $l$ and $r$ is equivalent to producing maximal entanglement between $R$ and $T$.\(^3\)

The traversable wormhole protocol is as follows (see see Fig. 1).

\(^2\)It would be interesting to study if these operators are easy to manipulate in some experimental realization of the SYK model.

\(^3\)Maximal entanglement between $R$ and $T$ means that they are in one of four Bell states, which are related to each other by a Pauli matrix operation.
1. At time $-t'$, apply a SWAP between Q and $l$ such that the qubit is inserted into the wormhole.

2. At time zero, apply an interaction $U = e^{i\mu V}$ with $V = \mathcal{O}_l \mathcal{O}_r$ to the state.

3. At time $t$, apply a SWAP between $T$ and $r$ such that the qubit is extracted from the wormhole.

In the first step, we need to find an appropriate SWAP operator. Since $l$ and $r$ contain Dirac fermions, we can pick one $\chi_l$ and its conjugate $\chi_l^\dagger$ with

$$\{\chi_l, \chi_l^\dagger\} = 1, \chi_l^2 = \chi_l^\dagger 2 = 0$$

and construct a SWAP operator as

$$S_{Ql} = \left( \begin{array}{cccc} \chi_l \chi_l^\dagger & \chi_l^\dagger \chi_l & 0 & 0 \\ \chi_l & \chi_l^\dagger & 0 & 0 \\ 0 & 0 & \chi_l & \chi_l^\dagger \\ 0 & 0 & \chi_l^\dagger & \chi_l \end{array} \right)$$

Note that this is the ordinary SWAP operator, as can be seen from the Pauli matrix representation for $\chi_l$ and $\chi_l^\dagger$:

$$\chi_l \approx \left( \begin{array}{cc} 0 & 1 \\ 0 & 0 \end{array} \right), \chi_l^\dagger \approx \left( \begin{array}{cc} 0 & 0 \\ 1 & 0 \end{array} \right)$$

In the final step of the protocol, we will use the same definition for the SWAP operator $S_{Tr}$ by replacing $l$ with $r$ in (2.6).

The second step can equivalently be replaced by measurement on the left together with action of a unitarity operator on the right, so that only a classical channel communication is required. The basic idea is that an interaction $e^{i\mu O_l O_r} = \sum_a P_a e^{i\mu O_r}$, where $P_a$ is the projector on to the eigensubspace of $O_l$ with eigenvalue $a$. Whether the value of $a$ is actually measured, that is, classically recorded, on the left cannot affect the result on the right [2].

Our protocol will involve a slight generalization, in which many operators are coupled, $e^{i\mu_0 \sum_j O^l_j O^r_j}$, which is equivalent to a classical channel only when the various $O^l_j O^r_j$ commute with each other. In particular, the construction will involve coupling the Majoranas, which can be written in terms of operations on the qubits using the above representation as

$$i\psi^{2j-1}_l \psi^{2j-1}_r = -\frac{1}{2} (XZ)_j, i\psi^{2j}_l \psi^{2j}_r = \frac{1}{2} (YY)_j$$

where $[\cdots]_j \equiv (II)^{j-1}[\cdots](II)^{N/2-j}$ means acting only on $j$-th left and right qubits.

It is straightforward to see that

$$e^{i\mu_0 j} \psi^{2j-1}_l \psi^{2j-1}_r = \left[ P_{x+} e^{-i\mu_0 Z/2} + P_{x-} e^{i\mu_0 Z/2} \right]_j$$

and

$$e^{i\mu_0 j} \psi^{2j}_l \psi^{2j}_r = \left[ P_{y+} e^{i\mu_0 Y/2} + P_{y-} e^{-i\mu_0 Y/2} \right]_j$$

Note that [2]
where \( P_x^\pm = (I \pm X)/2 \) and \( P_y^\pm = (I \pm Y)/2 \) are projectors onto eigenstates of \( X \) and \( Y \) respectively. Therefore each term in \( e^{i\phi \sum_j C_j^\dagger C_j} \) is of the form of \( \sum_n P_n^a U_n^a \), where each measurement is applied only on a single qubit. In standard teleportation, one usually implements a Bell pair measurement rather than a single qubit measurement in the computational basis. The extra simplicity in our situation is possible because of the scrambling generated by time evolution [9].

If we include Majorana fields with both \( 2j - 1 \) and \( 2j \) indices in the coupling \( V \), their projections will not commute, as shown in (2.9) and (2.10). Therefore, to relate to teleportation with a classical channel, one should consider coupling at most half of the \( N \) Majoranas, as discussed in Sec. 5.2.

After the three steps, the state becomes

\[
S_{TR} \mathcal{U} S_{Qi} |\phi_0\rangle_{RQ} |tfd\rangle_{lr} |0\rangle_T
= \frac{1}{\sqrt{2}} \left( |0\rangle_{TR} \otimes \chi_r \chi^\dagger_T + |1\rangle_{TR} \otimes \chi_T \chi^\dagger_r \right) \mathcal{U} \left( |00\rangle_{RQ} \otimes \chi_l \chi^\dagger_l \right) + |01\rangle_{RQ} \otimes \chi_l + |10\rangle_{RQ} \otimes \chi^\dagger_l \chi^\dagger_l |tfd\rangle_{lr} \right)
\]

(2.11)

where \( \chi_r, \chi^\dagger_T \) are short for \( \chi_r(t), \chi^\dagger_T(t) \) and \( \chi_l, \chi^\dagger_l \) are short for \( \chi_l(-t'), \chi^\dagger_l(-t') \). In the main part of this paper, we suppress their time arguments for notational simplicity.

In order to quantify the success of teleportation, we compute the mutual information between \( R \) and \( T \). Perfect teleportation corresponds to

\[
I_{RT} = S(R) + S(T) - S(RT) = 2 \log 2
\]

(2.12)

The reduced density matrix of \( TR \) is

\[
\rho_{TR} = \frac{1}{2} \begin{pmatrix}
\rho_{11} & 0 & 0 & \rho_{14} \\
0 & \rho_{22} & \rho_{23} & 0 \\
0 & \rho_{32} & \rho_{33} & 0 \\
\rho_{42} & 0 & 0 & \rho_{44}
\end{pmatrix}
\]

(2.13)

where the trivial matrix elements are due to fermion number conservation

\[
\langle \chi_{i_1} \cdots \chi_{i_s} \chi^\dagger_{i_{s+1}} \cdots \chi^\dagger_{i_{2k+1}} \rangle = 0, \ k \in \mathbb{N}
\]

(2.14)

and the nontrivial matrix elements are given as

\[
\rho_{11} = \langle \chi_i \chi^\dagger_i \mathcal{U}^\dagger \chi_r \chi^\dagger_r \mathcal{U} \chi_l \chi^\dagger_l \rangle + \langle \chi_i \mathcal{U}^\dagger \chi_r \chi^\dagger_r \mathcal{U} \chi_l \rangle
\]

(2.15)

\[
\rho_{14} = \langle \chi_i \mathcal{U}^\dagger \chi_r \chi^\dagger_r \mathcal{U} \chi_l \chi^\dagger_l \rangle + \langle \chi_i \mathcal{U} \chi^\dagger_r \chi_r \mathcal{U} \chi_l \rangle
\]

(2.16)

\[
\rho_{22} = \langle \chi_i \mathcal{U}^\dagger \chi_r \chi^\dagger_r \mathcal{U} \chi_l \chi^\dagger_l \rangle + \langle \chi_i \mathcal{U} \chi^\dagger_r \chi_r \mathcal{U} \chi_l \rangle
\]

(2.17)

\[
\rho_{23} = \langle \chi_i \mathcal{U}^\dagger \chi_r \chi^\dagger_r \mathcal{U} \chi_l \chi^\dagger_l \rangle + \langle \chi_i \mathcal{U} \chi^\dagger_r \chi_r \mathcal{U} \chi_l \rangle
\]

(2.18)

\[
\rho_{33} = \langle \chi_i \mathcal{U}^\dagger \chi_r \chi^\dagger_r \mathcal{U} \chi_l \chi^\dagger_l \rangle + \langle \chi_i \mathcal{U} \chi^\dagger_r \chi_r \mathcal{U} \chi_l \rangle
\]

(2.19)

\[
\rho_{44} = \langle \chi_i \mathcal{U}^\dagger \chi_r \chi^\dagger_r \mathcal{U} \chi_l \chi^\dagger_l \rangle + \langle \chi_i \mathcal{U} \chi^\dagger_r \chi_r \mathcal{U} \chi_l \rangle
\]

(2.20)
where \( \mathcal{U} \equiv \exp(i\mu V) \) and all expectation values are taken in thermofield double state. A consistency check is that if \( \mu = 0 \), then we get \( \rho_{TR} = \frac{1}{2} \mathrm{diag}(\rho_{11}, \rho_{11}, 1 - \rho_{11}, 1 - \rho_{11}) \) which leads to zero mutual information \( I_{RT} \).

Perfect teleportation (2.12) requires that both \( S(R) = S(T) = 2 \log 2 \) and \( S(RT) = 0 \). Given the structure of \( \rho_{TR} \) in (2.13), the first conditions imply that

\[
\rho_{11} = \rho_{44}, \quad \rho_{11} + \rho_{22} = \rho_{11} + \rho_{33} = 1 \tag{2.21}
\]

and second condition implies that either

\[
\begin{cases}
\rho_{11} = |\rho_{14}| = 1, & |\rho_{23}| = 0 \\
\rho_{11} = |\rho_{14}| = 0, & |\rho_{23}| = 1
\end{cases} \tag{2.22}
\]

Consider the first case. It is obvious that

\[
\rho_{11} + \rho_{33} = \left\langle \chi_l \chi_l^{\dagger} \mathcal{U} \{\chi_r, \chi_l^{\dagger}\} \mathcal{U} \chi_l \chi_l^{\dagger} \right\rangle + \left\langle \chi_l^{\dagger} \mathcal{U} \{\chi_r, \chi_l^{\dagger}\} \mathcal{U} \chi_l \chi_l^{\dagger} \right\rangle = \left\langle \{\chi_l, \chi_l^{\dagger}\} \right\rangle = 1 \tag{2.23}
\]

and similarly \( \rho_{22} + \rho_{44} = 1 \). Therefore, \( \rho_{11} = 1 \) is equivalent to \( \rho_{33} = 0 \), which implies that the two terms in (2.19) vanish, as both are nonnegative

\[
\chi_r \mathcal{U} \chi_l \chi_l^{\dagger} |\text{tdf}\rangle = \chi_r |\text{tdf}\rangle \tag{2.24}
\]

Similarly, \( \rho_{22} = 0 \) implies that

\[
\chi_l^{\dagger} \mathcal{U} \chi_l^{\dagger} |\text{tdf}\rangle = \chi_l^{\dagger} |\text{tdf}\rangle \tag{2.25}
\]

Based on these, \( \rho_{23} \) is automatically trivial. The only remaining nontrivial condition is \( |\rho_{14}| = 1 \). From (2.24) and (2.25), we can derive

\[
\begin{align*}
\chi_r \mathcal{U} \chi_l^{\dagger} |\text{tdf}\rangle &= \chi_r |\text{tdf}\rangle, \\
\chi_l^{\dagger} \mathcal{U} \chi_l^{\dagger} |\text{tdf}\rangle &= \chi_l^{\dagger} |\text{tdf}\rangle
\end{align*} \tag{2.26, 2.27}
\]

which can be used to simplify \( |\rho_{14}| = 1 \) to the condition

\[
\left| \left\langle \{\mathcal{U}^{\dagger} \chi_l^{\dagger} \mathcal{U}, \chi_l\} \right\rangle \right| = 1 \tag{2.28}
\]

This has a clear physical interpretation: the left-right causal propagator reaches its maximum value. Note that because we are discussing fermions, the propagator can never be larger than 1.

For the second possible case above, the condition for perfect teleportation is similar

\[
\begin{align*}
\rho_{11} = 0 &\implies \chi_l^{\dagger} \mathcal{U} \chi_l^{\dagger} |\text{tdf}\rangle = \chi_l^{\dagger} \mathcal{U} \chi_l |\text{tdf}\rangle = 0 \\
\rho_{44} = 0 &\implies \chi_r \mathcal{U} \chi_l^{\dagger} |\text{tdf}\rangle = \chi_r \mathcal{U} \chi_l |\text{tdf}\rangle = 0 \\
|\rho_{23}| = 1 &\implies \left| \left\langle \{\mathcal{U}^{\dagger} \chi_r \mathcal{U}, \chi_l\} \right\rangle \right| = 1
\end{align*} \tag{2.29, 2.30, 2.31}
\]

Comparing the two, one can see that the difference is just an exchange of \( \chi_r \) and \( \chi_l^{\dagger} \). This just corresponds to flipping the convention of which state on the right we call 0 versus 1. If we interpret \( \chi^{\dagger} \) as creation of a particle and \( \chi \) as annihilation of a particle, it is natural to take the first case.
2.2 SYK model

In the SYK model, we can construct Dirac fermions from two Majorana fermions. More precisely, we will consider an even number $N$ of Majorana fermions on each side:

$$H_{l,r} = i^{q/2} \sum_{1 \leq j_1 < \cdots < j_q \leq N} J^{l,r}_{j_1 \cdots j_q} \psi_{j_1}^{l,r} \cdots \psi_{j_q}^{l,r},$$  \hspace{1cm} (2.32)

$$\left\langle \left(J^{l,r}_{j_1 \cdots j_q}\right)^2\right\rangle = \frac{2^{q-1} J^2(q-1)!}{qN^{q-1}} = \frac{J^2(q-1)!}{N^{q-1}}$$  \hspace{1cm} (2.33)

where the normalization is

$$\{\psi_{j}^{l,r}, \psi_{k}^{l,r}\} = \delta_{jk}$$  \hspace{1cm} (2.34)

Let $|I\rangle$ be the maximally entangled state of $l$ and $r$ defined by

$$(\psi_{j}^{l} + i\psi_{j}^{r}) |I\rangle = 0, \hspace{1cm} \forall i$$  \hspace{1cm} (2.35)

In other words, $|I\rangle$ is annihilated by a complex fermion $f_j = \frac{1}{\sqrt{2}}(\psi_{j}^{l} + i\psi_{j}^{r})$.

The thermofield double state is then given by

$$|\text{tfd}\rangle = Z_\beta^{-1/2} e^{-\beta H/4} |I\rangle, \hspace{1cm} H \equiv H_l + H_r$$  \hspace{1cm} (2.36)

We further require that $H_l - H_r |I\rangle = 0$ so this state is the infinite temperature entangled state. Using $(H_l - H_r) |I\rangle = 0$, this implies that the Hamiltonia must be related by

$$J^{l}_{j_1 \cdots j_q} = i^{q} J^{r}_{j_1 \cdots j_q}$$  \hspace{1cm} (2.37)

The SYK model can be solved using path integrals after averaging over the Gaussian ensemble of random coupling $J$. Note that the thermofield double state is defined by a Euclidean evolution of length $\beta/4$ from $|I\rangle$. Euclidean time ordered correlation functions in the thermofield double state are related to

$$\left\langle I|e^{-\beta H/2} T\mathcal{O}_1 \cdots \mathcal{O}_k |I\right\rangle$$  \hspace{1cm} (2.38)

which is equivalent to the path integral over a length of $\beta/2$.\footnote{If we take all $\mathcal{O}_i$ at $\beta/4$, this is the expectation value in the thermofield double state.} Therefore, the action we start with is

$$S = \int_0^{\beta/2} d\tau \left\{ \frac{1}{2} \sum_{i=1}^{N} (\psi_{i}^l \partial_\tau \psi_{i}^l + \psi_{i}^r \partial_\tau \psi_{i}^r) + H_l + H_r \right\}$$  \hspace{1cm} (2.39)

Since we have two copies with random couplings related by (2.37), integrating over $J$ will give interaction terms between $\psi_{l}$ and $\psi_{r}$ \cite{16}. Introducing four delta functions

$$\delta \left( G_{ab}(\tau_1, \tau_2) - \frac{1}{N} \sum_{i=1}^{N} \psi_{a}^i(\tau_1) \psi_{b}^i(\tau_2) \right)$$  \hspace{1cm} (2.40)
for \( a, b = l, r \) in the path integral, we find

\[
S = \frac{1}{2} \int_0^{\beta/2} d\tau \sum_{i=1}^{N} (\psi_i^a \partial_\tau \psi_i^a + \psi_i^a \partial_\tau \psi_i^a) - \frac{1}{2} \sum_{a,b} \int_0^{\beta/2} d\tau d\tau' \Sigma_{ab}(\tau, \tau') \sum_{i=1}^{N} \psi_i^a(\tau) \psi_i^a(\tau')
\]

\[
+ \frac{N}{2} \sum_{a,b} \int_0^{\beta/2} d\tau d\tau' \left[ \Sigma_{ab}(\tau, \tau') G_{ab}(\tau, \tau') - \frac{J^2}{q} s_{ab} G_{ab}(\tau, \tau') \right]
\]

(2.41)

where \( s_{ll} = s_{rr} = 1 \) and \( s_{lr} = s_{rl} = (-)^q/2 \). We stitch together the left and right fermions into a single field, defining \( \psi \) for \( \tau \in [0, \beta] \) as

\[
\psi^j(\tau) = \begin{cases} 
\psi^j_1(\tau) & \tau \in [0, \beta/2] \\
\psi^j_2(\beta - \tau) & \tau \in [\beta/2, \beta] 
\end{cases}
\]

(2.42)

and corresponding \( G, \Sigma \) fields

\[
G(\tau, \tau'), \Sigma(\tau, \tau')
\]

\[
= \begin{cases} 
G_{ll}(\tau, \tau'), \Sigma_{ll}(\tau, \tau') & \tau, \tau' \in [0, \beta/2] \\
iG_{lr}(\tau, \tau'), -i\Sigma_{lr}(\tau, \tau') & \tau, \tau' \in [0, \beta/2] \\
iG_{rl}(\tau_\beta, \tau'), -i\Sigma_{rl}(\tau_\beta, \tau') & \tau_\beta, \tau' \in [0, \beta/2] \\
-G_{rr}(\tau_\beta, \tau'_\beta), -\Sigma_{rr}(\tau_\beta, \tau'_\beta) & \tau_\beta, \tau'_\beta \in [0, \beta/2] 
\end{cases}
\]

(2.43)

where \( \tau_\beta \equiv \beta - \tau \). The action then simplifies to

\[
S = \frac{1}{2} \sum_{i=1}^{N} \left[ \int_0^{\beta} d\tau \psi^i_1 \partial_\tau \psi^i_1 - \int_0^{\beta} d\tau d\tau' \psi^i(\tau) \Sigma(\tau, \tau') \psi^i(\tau') \right]
\]

\[
+ \frac{N}{2} \int_0^{\beta} d\tau d\tau' \left[ \Sigma(\tau, \tau') G(\tau, \tau') - \frac{J^2}{q} G(\tau, \tau') \right]
\]

(2.44)

which unsurprisingly becomes the path integral of a single field \( \psi \) on the thermal circle of length \( \beta \). The only thing to check in this treatment is that on the stitching boundary \( \beta/2 \), the field redefinition may not be smooth. Fortunately, if we extend the definition of \( \psi^i_{l,r} \) beyond \( \tau = \beta/2 \) via Euclidean evolution, we have

\[
\langle I | e^{-\beta H/2} \psi^i_1(\beta/2 + \tau) = \langle I | e^{H^r \tau} \psi^i_1 e^{-\beta(\beta/2 + \tau)H}
\]

\[
= \langle I | \psi^i_1 e^{2H^r \tau} e^{-\beta(\beta/2 + \tau)H} = i \langle I | e^{-\beta H/2} \psi^i_1(\beta/2 - \tau)
\]

(2.45)

thanks to (2.35). This shows that the fields in the path integral are smoothly defined at \( \tau = \beta/2 \). Moreover, one can similarly show that

\[
\psi^i_1(-\tau) | I \rangle = -i\psi^i_2(\tau) | I \rangle
\]

(2.46)

which means that we can even extend the path integral past \( \tau = \beta \) by requiring the usual thermal anti-periodic \( \psi^i(\tau) = -\psi^i(\beta + \tau) \) boundary condition. Integration over \( \psi^i \) results in an effective action for the \( G \) and \( \Sigma \) fields.

\[
S[G, \Sigma] = -\frac{N}{2} \log \det(\partial_\tau - \Sigma) + \frac{N}{2} \int \int (\Sigma G - \frac{1}{q} J^2 G^q)
\]

(2.47)
In the large $N$ limit, the equation of motion is
\begin{align}
G^{-1} &= G_0^{-1} - \Sigma, \quad \Sigma(\tau, \tau') = J^2 G(\tau, \tau')^{g-1}, \\
G_0^{-1} &= \partial_\tau \iff G_0(\tau) = \frac{1}{2} \text{sgn} \tau
\end{align}
(2.48)
(2.49)

We will add instantaneous interactions between the two SYK systems at time $\tau_0$ by
[16]
\begin{equation}
H_{int} = -\mu V = -\mu \times \frac{i}{qN} \sum_{j=1}^{N} \psi^j_d \psi^j_r = -\frac{\mu}{qN} \sum_{j=1}^{N} f_j^\dagger f_j + \frac{\mu}{2q}
\end{equation}
(2.50)
We will take $\mu$ to be $O(1)$ in the $1/N$ counting, as in previous work [2, 26]. Thus $\mu V$ has an $O(1)$ effect on the state $|I\rangle$, namely
\begin{equation}
\mu V |I\rangle = -\frac{\mu}{2q} |I\rangle
\end{equation}
(2.51)
Writing $H_{int}$ in terms of $G$ field, the action is shifted by
\begin{equation}
\delta S = -\frac{\mu}{2q} [G(\tau_0, \beta - \tau_0) - G(\beta - \tau_0, \tau_0)]
\end{equation}
(2.52)
Such an instantaneous interaction does not affect the equation of motion but only changes the boundary condition of $G$ and $\Sigma$ at $\tau_0$ (see Sec. 3.1.2).

It turns out that
\begin{equation}
\Sigma(\tau, \tau') = J^2 G(\tau, \tau')^{g-1} + \frac{\mu}{qN} \left[ \delta_{\tau, \tau_0} \delta_{\tau', \beta - \tau_0} - \delta_{\tau, \beta - \tau_0} \delta_{\tau', \tau_0} \right]
\end{equation}
(2.53)
where $\delta_{a,b}$ is short for $\delta(a - b)$. On the other hand, $G^{-1} = G_0^{-1} - \Sigma$ can be written as
\begin{equation}
\partial_\tau G(\tau', \tau) - \int d\tau'' \Sigma(\tau', \tau'') G(\tau'', \tau) = \delta(\tau - \tau')
\end{equation}
(2.54)
Integrating $\tau'$ around $\tau_0$ and $\beta - \tau_0$ respectively, we get
\begin{align}
G(\tau_0, \tau) - G(\tau_0 - \epsilon, \tau) &= \frac{\mu}{qN} G(\beta - \tau_0, \tau) \\
G((\beta - \tau_0) + \epsilon, \tau) - G((\beta - \tau_0) - \epsilon, \tau) &= \frac{\mu}{qN} G(\tau_0, \tau)
\end{align}
(2.55)
(2.56)
where subscript in $\tau_{\pm}$ means $\tau \pm \epsilon$ for $\epsilon \to 0$. Note that the RHS of above equations are not defined $a\ priori$, since $\tau_0$ and $\beta - \tau_0$ are singular points. Instead these two equations should be taken as the definition of the values of $G$ at these two points, as follows. Consider the expansion of $G$ as a series in powers of $\mu$, so at leading order $G$ is continuous. Hence, the discontinuity of $G$ around $\tau_0$ and $\beta - \tau_0$ at linear order in $\mu$ is given by the zero-th order value of $G$ on the RHS.\footnote{Beyond linear order, it is not clear how to determine the discontinuity directly from (2.55) and (2.56).} This is exactly the linearized version of twist boundary condition of $G$ we will derive from the microscopic fermion description in Sec. 3.1.2.
2.3 Density matrix $\rho_{TR}$ in SYK model

For each of the pair of SYK systems, we construct Dirac fermions by combining two Majorana fermions

$$\chi_{l,r}^j = \frac{1}{\sqrt{2}}(\psi_{l,r}^{2j-1} + i\psi_{l,r}^{2j}), \quad \chi_{l,r}^j = \frac{1}{\sqrt{2}}(\psi_{l,r}^{2j-1} - i\psi_{l,r}^{2j})$$

with commutation relations

$$\{\chi_{l,r}^j, \chi_{l,r}^{j'}\} = \delta^{jj'}$$

It follows that

$$\chi_{l,r}^j \chi_{l,r}^{j'} = \frac{1}{2} - i\psi_{l,r}^{2j-1}\psi_{l,r}^{2j}, \quad \chi_{l,r}^j \chi_{l,r}^{j'} = \frac{1}{2} + i\psi_{l,r}^{2j-1}\psi_{l,r}^{2j}$$

Using above constructions, we can write down the matrix element of $\rho_{TR}$ as the Dirac fermion appearing in the general protocol described in section 2.1. Take $\rho_{11}$ as an example. The first term is

$$\langle \chi_l^1 \chi_l^1 U^\dagger \chi_r^1 \chi_r^1 U \chi_l^1 \chi_l^1 \rangle = \frac{1}{2} \langle \chi_l^1 \chi_l^1 \rangle - \frac{i}{4} \langle U^\dagger \psi_l^1 \psi_l^2 U \rangle - \frac{1}{2} \langle \{\psi_l^1, U^\dagger \psi_l^1 \psi_l^2 U\} \rangle + i \langle \psi_l^1 \psi_l^2 U^\dagger \psi_l^1 \psi_l^2 U \psi_l^2 \rangle$$

The second term is

$$\langle \chi_l^1 U^\dagger \chi_l^1 U \chi_l^1 \chi_l^1 \rangle = \frac{1}{2} \langle \chi_l^1 \chi_l^1 \rangle - \frac{i}{2} \langle \psi_l^1 U^\dagger \psi_l^1 \psi_l^2 \psi_l^2 \rangle - \frac{1}{2} \langle \psi_l^2 U^\dagger \psi_l^1 \psi_l^2 \psi_l^1 \rangle + \frac{1}{2} \langle \psi_l^2 U^\dagger \psi_l^1 \psi_l^2 \psi_l^2 \rangle - \frac{i}{2} \langle \psi_l^2 U^\dagger \psi_l^1 \psi_l^2 \psi_l^2 \rangle$$

For the SYK model, after performing the ensemble average, there is an emergent $SO(N)$ symmetry that rotates all $\psi_l^i$ by $U^\dagger \psi_l^i$. This symmetry must be manifested by correlation functions, thus

$$\langle \psi_1^{i_1} \cdots \psi_2^{k_2} \rangle \propto \delta^{\pi_1 \pi_2} \cdots \delta^{\pi_{2k-1} \pi_{2k}}$$

where $\pi_i$ is the permutation of $\{i_1, \cdots, i_{2k}\}$. As $V$ contains all pairs of $\psi_l^i$ and $\psi_r^i$ with the same indices, the correlation functions in (2.60) and (2.61) with an odd number of 1 and 2 indices vanish. Moreover, this symmetry dictates that correlation functions are invariant under exchange of the 1 and 2 indices. Therefore, we get

$$\rho_{11} = \frac{1}{2} \left[ 1 - \langle \{\psi_l^1, [\psi_l^1, U^\dagger \psi_l^1 \psi_l^2 U]\} \rangle \right]$$

Similarly, we can work out all other matrix elements of $\rho_{TR}$. They are

$$\rho_{14} = \frac{1}{2} \langle \{\psi_l^1, U^\dagger \psi_l^1 U\} \rangle - \langle \{\psi_l^2, [\psi_l^1, U^\dagger \psi_l^1 \psi_l^2 U]\} \rangle$$

$$\rho_{22} = \frac{1}{2} \left[ 1 + \langle \{\psi_l^1, [\psi_l^2, U^\dagger \psi_l^1 \psi_l^2 U]\} \rangle \right] = 1 - \rho_{11}$$

$$\rho_{23} = 0, \quad \rho_{33} = 1 - \rho_{11}, \quad \rho_{44} = 1 - \rho_{22}$$

Note that in (2.66) $\rho_{23}$ becomes trivial exactly due to the $SO(N)$ symmetry, while $\rho_{33}$ and $\rho_{44}$ are related to $\rho_{11}$ and $\rho_{22}$ by definition. Comparing with the conditions for perfect teleportation (2.21) and (2.22), the only nontrivial conditions for obtaining maximal mutual information between R and T are

$$\rho_{11} = |\rho_{14}| = 1$$
3 Computing the correlation functions in the SYK model

In this section, we will use the method developed in [27]. To calculate $\rho_{11}$ and $\rho_{14}$, there are two types of correlation functions that need to be found

$$\langle e^{-\mu V} \psi^1 e^{i\mu V} \psi^1 \rangle, \quad \langle e^{-\mu V} \psi^1 e^{i\mu V} \psi^2 \rangle$$

(3.1)

where we will consider all orderings of the operators. We first focus on the former. For notational simplicity, in this section we use $\psi$ to represent $\psi^1$.

3.1 Stitching correlation function

With the stitching field $\psi$ defined in (2.42), we define a stitching correlation function for $\tau_a, \tau_b \in [0, \beta]$ as

$$G_\mu(\tau_a, \tau_b) = \frac{\langle I e^{-\beta H/2} \mathcal{T} [e^{-\mu V(\beta/4+\epsilon)} e^{\mu V(\beta/4-\epsilon)} \psi(\tau_a) \psi(\tau_b)] I \rangle}{\langle I e^{-\beta H/2} e^{-\mu V(\beta/4+\epsilon)} e^{\mu V(\beta/4-\epsilon)} I \rangle} \text{sgn}(\bar{\tau}_a - \bar{\tau}_b)$$

(3.2)

where $\bar{\tau} \equiv \min(\tau, \beta - \tau)$ and $\mathcal{T}$ represents time ordering for $\bar{\tau}_a$ and $\bar{\tau}_b$ (without any $\pm$ sign from (anti-)commutation of $\psi$). Here $\epsilon \in (0, \beta/4)$ is a regulator that we will ultimately take to zero. As discussed in Sec. 2.2, this correlation function is smoothly defined around $\beta/2$. Note that $G_\mu$ clearly can be extended to any real $\tau_a$ and $\tau_b$ using the periodicity of $\psi$, $\psi(\tau + \beta) = -\psi(\tau)$. We will call $\tau_a, \tau_b \in [0, \beta]$ the basic domain (see Fig. 2).

3.1.1 Symmetries

There are several symmetries of $G_\mu$. It is anti-symmetric in $\tau_a$ and $\tau_b$

$$G_\mu(\tau_a, \tau_b) = -G_\mu(\tau_b, \tau_a)$$

(3.3)

which together with the periodicity can be summarized as

$$G_\mu(\tau_a, \tau_b) = -G_\mu(\tau_b, \tau_a) = (-)^{n+m} G_\mu(\tau_a + n \beta, \tau_b + m \beta)$$

(3.4)

Another feature is that $G_\mu$ is real. This can be seen as follows. First, the Hamiltonians $H_{l,r}$ have only real coefficients and $\mu$ is real. Second, $\psi^1_l = \frac{1}{\sqrt{2}} (f^*_l + f^*_r)$ and $i \psi^2_l = -\frac{1}{\sqrt{2}} (f^*_l - f^*_r)$ are linear combinations with real coefficients. Hence we can easily conclude that as operators both $e^{-\beta H/2} \mathcal{T} [e^{-\mu V(\beta/4+\epsilon)} e^{\mu V(\beta/4-\epsilon)} \psi(\tau_a) \psi(\tau_b)]$ and $e^{-\beta H/2} e^{-\mu V(\beta/4+\epsilon)} e^{\mu V(\beta/4-\epsilon)}$ consist of $c_i$ and $c_i^*$ with real coefficients. Thus $G_\mu$ must be real.

This leads to further symmetries. Define $\mathcal{O}^l = \psi_l, \mathcal{O}^r = i \psi_r$ and

$$\mathcal{C}^{AB}_\pm(\tau_1, \tau_2) = \mathcal{T} \left[ e^{-\mu V(\beta/4+\epsilon)} e^{\mu V(\beta/4-\epsilon)} \mathcal{O}^A(\tau_1) \mathcal{O}^B(\tau_2) \right]$$

(3.5)

For $\bar{\tau}_a, \bar{\tau}_b \in [0, \beta/2]$ and $A, B = l, r$, we have

$$\langle I e^{-\beta H/2} \mathcal{C}^A_+(\bar{\tau}_a, \bar{\tau}_b) I \rangle^* = (-1)^s \langle I e^{-\beta H/2} \mathcal{C}^A_-(\beta/2 - \bar{\tau}_a, \beta/2 - \bar{\tau}_b) I \rangle$$

(3.6)
where \( s = 0 \) if \( A = B \) and \( s = 1 \) if \( A \neq B \) (because there is an \( i \) with \( \psi_r \)), and \( T \) is ordinary time ordering. Here we used the fact
\[
\mathcal{O}(\tau)^\dagger = [e^{H\tau} \mathcal{O} e^{-H\tau}]^\dagger = e^{-H\tau} \mathcal{O} e^{H\tau} = \mathcal{O}(-\tau)
\] (3.7)
This implies that in the basic domain \( \tau_a, \tau_b \in [0, \beta] \)
\[
\mathcal{G}_\mu(\tau_a, \tau_b) = \mathcal{G}_{-\mu}(\beta/2 - \tau_b, \beta/2 - \tau_a)
\] (3.8)
Using this symmetry and shifts by \( \beta \), we get another symmetry
\[
\mathcal{G}_\mu(\tau_a, \tau_b) = \mathcal{G}_{-\mu}(3\beta/2 - \tau_a, \beta/2 - \tau_b)
\] (3.9)
\[
= \mathcal{G}_{-\mu}(3\beta/2 - \tau_b, 3\beta/2 - \tau_a)
\] (3.10)
Finally, if \( q \in 4\mathbb{Z} \) there is one more discrete symmetry of \( \mathcal{G}_\mu \) resulting from
\[
\psi^j_l \rightarrow \psi^j_r, \quad \psi^j_r \rightarrow -\psi^j_l
\] (3.11)
This can be seen by noting that \( \mathcal{G}_\mu \) is the expectation of a complicated operator that can be expanded as a sum of various products of \( \psi^j_l \) and \( \psi^j_r \) in the state \(|I\rangle\). Since \(|I\rangle\) is defined by \((\psi^j_l + i\psi^j_r) |I\rangle = 0\) for all \( j \), \(|I\rangle\) has a tensor product form \( \otimes_j |I_j\rangle \). Therefore, we only need to check if all correlations in each \(|I_j\rangle\) are invariant under (3.11). It is clear that for all \( j \)
\[
\langle I_j | \psi^j_l \psi^j_r | I_j \rangle = \frac{i}{2} \langle I_j | \psi^j_r | I_j \rangle = \langle I_j | \psi^j_l | I_j \rangle = 0
\] (3.12)
and all higher point correlations can be reduced to them using (2.34). This means that whatever \( \mathcal{G}_\mu \) is, the whole expression is invariant under (3.11). Second, \( V \) is invariant
\[
V = i \sum_j \psi^j_l \psi^j_r = i \sum_j \psi^j_r (-\psi^j_l) = i \sum_j \psi^j_l \psi^j_r
\] (3.13)
Third the Hamiltonian \( H \) is invariant when \( q \in 4\mathbb{Z} \) as then \( J^l = J^r \). Hence we have the following identity
\[
\mathcal{G}_\mu(\tau_a, \tau_b) = -\mathcal{G}_\mu(\beta - \tau_a, \beta - \tau_b) = \mathcal{G}_\mu(\beta - \tau_b, \beta - \tau_a)
\] (3.14)
These symmetries kill some regions in the left top triangle in the basic domain. Indeed, (3.8) and (3.10) says \( \tau_a + \tau_b = \beta/2 \), \( 3\beta/2 \) are two invariant lines, which kill the regions \( A \) and \( B \) in Fig. 2. (3.9) implies the existence of a reflection symmetry around point \((\tau_a, \tau_b) = (3\beta/4, \beta/4)\) which kills region \( C \). (3.14) says \( \tau_a + \tau_b = \beta \) is an invariant line, which kills region \( D \). In the end, the only independent region is the dark yellow square in Fig. 2, which we will call the fundamental region.
Figure 2: The stitching correlation function $G_\mu$ in the basic domain is split into a few small regions. Due to symmetries, the independent region is the dark yellow one, which we call the fundamental region. Blue dashed lines are invariant under symmetries of $G_\mu$, which implies that the white dotted regions $A, B, C, D$ are not independent. The twisted boundary condition is on the four red lines, which split the fundamental domain further into five subregions $a, b, c, d, e$.

3.1.2 Twist boundary condition

The boundary conditions on the fermions induced by the instantaneous interaction result from the following identity

$$e^{\mu V} \left( \frac{\psi_l}{i \psi_r} \right) e^{-\mu V} = \begin{pmatrix} \cosh \frac{\mu}{qN} - \sinh \frac{\mu}{qN} \
\sinh \frac{\mu}{qN} & \cosh \frac{\mu}{qN} \end{pmatrix} \left( \frac{\psi_l}{i \psi_r} \right)$$

(3.15)

When $\psi$ moves across $\beta/4 \pm \epsilon$, it gets acted upon by the above connection equation (and its $-\mu$ version). It follows that for the stitching field $\psi$

$$\lim_{\tau \to (\beta/4 \mp \epsilon)_-} \left( \frac{\psi(\tau)}{\psi(\beta - \tau)} \right) = \begin{pmatrix} \cosh \frac{\mu}{qN} \mp \sinh \frac{\mu}{qN} \
\mp \sinh \frac{\mu}{qN} & \cosh \frac{\mu}{qN} \end{pmatrix} \lim_{\tau \to (\beta/4 \pm \epsilon)_+} \left( \frac{\psi(\tau)}{\psi(\beta - \tau)} \right)$$

(3.16)

As $G_\mu$ contains two $\psi$ insertions, this gives a twist boundary condition

$$\lim_{\tau_a, \tau_b \to (\beta/4 \mp \epsilon)_+} G_\mu(\tau_a, \tau_b) = \begin{pmatrix} \cosh \frac{\mu}{qN} \pm \sinh \frac{\mu}{qN} \
\pm \sinh \frac{\mu}{qN} & \cosh \frac{\mu}{qN} \end{pmatrix} \lim_{\tau_a, \tau_b \to (\beta/4 \pm \epsilon)_-} G_\mu(\tau_a, \tau_b)$$

$$\lim_{\tau_a, \tau_b \to (3\beta/4 \pm \epsilon)_-} G_\mu(\tau_a, \tau_b) = \lim_{\tau_a, \tau_b \to (3\beta/4 \pm \epsilon)_+} G_\mu(\tau_a, \tau_b)$$

(3.17)

Using the symmetries we can rewrite everything in terms of twist boundary conditions in fundamental region. Indeed, we have

$$G_\mu(\tau_a, (3\beta/4 \pm \epsilon)_-) = -G_\mu(\beta - \tau_a, (\beta/4 \mp \epsilon)_+)$$

(3.18)

$$G_\mu((\beta/4 - \epsilon)_\mp, \tau_b) = -G_{-\mu}((\beta/4 + \epsilon)_\mp, \beta/2 - \tau_b)$$

(3.19)

$$G_\mu((3\beta/4 + \epsilon)_\mp, \tau_b) = G_{-\mu}((3\beta/4 - \epsilon)_\pm, \beta/2 - \tau_b)$$

(3.20)
Figure 3: The smoothness condition for $G_{\mu}$. $G_{\mu}$ needs to be smooth in each region bounded by dashed and solid red lines. On dashed red lines, $G_{\mu}$ must satisfy a twist boundary condition, and on solid red lines, $G_{\mu}$ need not be smooth. Blue dashed lines are symmetry lines on which $G_{\mu}$ must be smooth. Due to the symmetry, we only need to solve for $G_{\mu}$ on the five regions $a, b, c, d, e$.

It follows that the independent twist boundary conditions in fundamental region are

\[
\begin{pmatrix}
G_{\mu}(\beta/4 + \epsilon +, \tau_b) \\
G_{\mu}(3\beta/4 - \epsilon, \tau_b)
\end{pmatrix} = \begin{pmatrix}
\cosh \frac{\mu}{qN} - \sinh \frac{\mu}{qN} \\
- \sinh \frac{\mu}{qN} \cosh \frac{\mu}{qN}
\end{pmatrix} \begin{pmatrix}
G_{\mu}(\beta/4 + \epsilon -, \tau_b) \\
G_{\mu}(3\beta/4 - \epsilon, \tau_b)
\end{pmatrix}
\]

and

\[
G_{\mu}(\tau_a, (\beta/4 \mp \epsilon)_+) = \cosh \frac{\mu}{qN} G_{\mu}(\tau_a, (\beta/4 \mp \epsilon)_-) \mp \sinh \frac{\mu}{qN} G_{\mu}(\beta - \tau_a, (\beta/4 \mp \epsilon)_-) (3.22)
\]

They are on the red dashed lines in Fig. 2, and separate the fundamental region into five subregions $a, b, c, d, e$. One can check that at linear order in $1/N$, the twist boundary conditions are the same as (2.55) and (2.56).

3.1.3 Smoothness and UV conditions

Although the symmetries reduced the problem to the fundamental region, that does not mean that we can take an arbitrary function that satisfies the twist boundary conditions and simply transform it to the other regions via the symmetry. In particular, the correlation function $G_{\mu}$ should be further constrained by smoothness and UV conditions.

The smoothness condition is that $G_{\mu}$ must be a smooth function of $\tau_{a,b}$ when no operators coincide with each other. It follows that $G_{\mu}$ must be smooth crossing certain symmetry lines, for example, the lines $\tau_a = \pm \tau_b + \beta/2$. On the other hand, some symmetry lines are “hard” lines that correspond to coincident operators, for example, $\tau_a = \pm \tau_b$ and $\tau_a = \pm \tau_b + \beta$. In the latter case, $G_{\mu}$ need not be smooth and the extension across them is simply to “copy and paste” by the symmetry.
In doing this, we need to study \( \mathcal{G}_\mu \) on a bigger patch as shown in Fig. 3. In this figure, \( \mathcal{G}_\mu \) needs to be smooth in each region bounded by dashed and solid red lines. On dashed red lines, \( \mathcal{G}_\mu \) must satisfy the twist boundary condition, and on solid red lines, \( \mathcal{G}_\mu \) need not be smooth. Blue dashed lines are symmetry lines on which \( \mathcal{G}_\mu \) must be smooth.

The input from the UV is that when \( \tau_a \to \tau_b \), \( \mathcal{G}_\mu \) must equal \( 1/2 \), which are required by the Majorana fermion algebra. This gives a boundary condition on the line \( \tau_a = \tau_b \).

Due to the symmetry, we only need to solve for \( \mathcal{G}_\mu \) on the new five subregions \( a, b, c, d, e \) in Fig. 3.

### 3.2 Large \( q \) solution

#### 3.2.1 General solution

The insertion of \( e^{\pm \mu V} \) in the correlation function \( \mathcal{G}_\mu \) can be understood as adding a deformation to action at \( \beta/4 \pm \epsilon \) of the form of (2.52). This does not change the bulk equation of motion (2.48), but simply imposes the twist boundary condition we analyzed above.

If we fix \( J \), the large \( q \) limit will truncate (2.48) to first order \([15, 28, 29]\) as

\[
[\mathcal{G}] = [\mathcal{G}_0] + \frac{\mathcal{J}^2}{q} \langle 2\mathcal{G} \rangle^{q-1}
\]

where \([A][B]\) means product by integrating over the intermediate variable \( \tau \). We make the ansatz for \( \tau_{ab} > 0 \)

\[
\mathcal{G}(\tau_a, \tau_b) = \mathcal{G}_0(\tau_{ab}) e^{\sigma(\tau_a, \tau_b)/(q-1)} \implies \mathcal{G}(\tau_a, \tau_b) = \frac{\mathcal{J}^2}{q} e^{\sigma(\tau_a, \tau_b)}
\]

Taking time derivative of \([G]\) in (3.23), we get

\[
\partial_a \partial_b (\mathcal{G} - \mathcal{G}_0) = -\frac{\mathcal{J}^2}{q} e^{\sigma(\tau_a, \tau_b)}, \quad \tau_{ab} > 0
\]

In the large \( q \) limit, this becomes

\[
\partial_a \partial_b \sigma = -2\mathcal{J}^2 e^{\sigma(\tau_a, \tau_b)}
\]

which is the well-known Liouville equation. The most general solution is

\[
\sigma = \ln \frac{f'(\tau_a)g'(\tau_b)}{(1 + \mathcal{J}^2 f(\tau_a)g(\tau_b))^2}
\]

It follows that the general solution for \( \mathcal{G} \) in the large \( q \) limit is

\[
\mathcal{G}(\tau_a, \tau_b) = \mathcal{G}_0(\tau_{ab}) \left[ \frac{f'(\tau_a)g'(\tau_b)}{(1 + \mathcal{J}^2 f(\tau_a)g(\tau_b))^2} \right]^{\frac{1}{q-1}}
\]

This solution has a global \( SL(2) \) symmetry. Under the following transformation

\[
f(x) \to \frac{a + bf(x)}{c + df(x)}, \quad g(x) \to \frac{d - c\mathcal{J}^2 g(x)}{\mathcal{J}^2(-b + a\mathcal{J}^2 g(x))},
\]

where \( bc - ad = 1 \), (3.27) is invariant.\(^6\) This global \( SL(2) \) symmetry is a gauge redundancy in the expression of \( \mathcal{G} \). In the following, we will discuss the solution for \( \mathcal{G} \) modulo this redundancy.

\(^6\)Note that overall scaling of \( a, b, c, d \) does not change \( f \), and thus we only the \( SL(2) \) subgroup of \( GL(2) \) acts non-trivially.
3.2.2 Translation invariant solution: $\mu = 0$ case

When $\mu = 0$, $G_\mu = G$ becomes the usual time translation invariant thermal correlation function. This means that $G(\tau_a, \tau_b)$ is a function of $\tau = \tau_{ab}$ only. In particular, $\partial_b = -\partial_a$ in the differential equation (3.26) and we get

$$\partial^2_\tau \sigma(\tau) = 2 J^2 e^{\sigma(\tau)}$$  \hspace{1cm} (3.30)

The general solution to this is

$$e^{\sigma(\tau)} = \frac{\omega^2}{J^2 \cos^2(\omega \tau + v)}$$  \hspace{1cm} (3.31)

where $\omega$ and $v$ are two integral constants. If we set $\tau_b = 0$ and $\tau_a = \tau$, we can compare it with (3.27) and find

$$f(\tau) = \frac{A + B \tan(\omega \tau + v)}{C + D \tan(\omega \tau + v)}$$  \hspace{1cm} (3.32)

where $A, B, C, D$ are some constants involving $g(0)$. We fix the $SL(2)$ symmetry by choosing

$$f(\tau) = \frac{1}{J} \tan(\omega \tau + v_1)$$  \hspace{1cm} (3.33)

Assume $g(\tau) = \frac{1}{J} \tan \omega \tilde{g}(\tau)$. Plugging this into (3.27) we find

$$e^{\sigma(\tau_a, \tau_b)} = \frac{\omega^2 \tilde{g}'(\tau_b)}{J^2 \cos^2(\omega \tau_a - \omega \tilde{g}(\tau_b) + v_1)}$$  \hspace{1cm} (3.34)

Comparing with (3.31), it is easy to see that $\tilde{g}(\tau_b) = \tau_b + v_2$ for some constant $v_2$.

In the following, Sec. 3.2.3, and Appendix A, we will shift $\tau_a$ to $\tau_a \rightarrow \tau_a + \beta/2$ to simplify the action of the symmetries. In these shifted coordinates, the symmetries discussed in subsection 3.1.1 now become (as $\mu = 0$)

$$(f(\tau_a), g(\tau_b)) \simeq (g(\tau_a), f(\tau_b)) \simeq (g(-\tau_a), f(-\tau_b))$$  \hspace{1cm} (3.35)

where $\simeq$ means equivalent under global $SL(2)$ transformation (3.29), namely the $\sigma$ value is the same. This restricts $v_2 = v_1 = v$. We summarize the translation invariant solution as follows

$$f(\tau) = g(\tau) = \frac{\tan(\omega \tau + v)}{J}, \quad e^\sigma = \frac{\omega^2}{J^2 \cos^2 \omega \tau_{ab}}$$  \hspace{1cm} (3.36)

The UV condition states that when $\tau_a = \tau_b - \beta/2$, we must have that $e^\sigma = 1$. This determines

$$\omega = J \cos \omega \beta/2$$  \hspace{1cm} (3.37)
3.2.3 Twist solution at large $q$

Let us move to nonzero $\mu$ case. The twist boundary condition makes it hard to find $f$ and $g$ across the various subregions of the fundamental region. However, as the coupling scales as $1/q$, the twist boundary condition significantly simplifies in the large $q$ limit. At order $1/q$, (3.22) and (3.21) become

$$
\sigma(\tau_a, (\beta/4 \mp \epsilon)_+) = \sigma(\tau_a, (\beta/4 \mp \epsilon)_-) \mp \mu/N
$$

(3.38)

$$
\sigma((-\beta/4 + \epsilon)_+, \tau_b) = \sigma((-\beta/4 + \epsilon)_-, \tau_b) - \mu/N
$$

(3.39)

$$
\sigma((\beta/4 - \epsilon)_-, \tau_b) = \sigma((\beta/4 - \epsilon)_+, \tau_b) - \mu/N
$$

(3.40)

which means that two twisted components decouple. All of these conditions can be written in the following form

$$
\frac{f_1(\tau_a)g_1'(\tau_b)}{(1 + J^2 f_1(\tau_a)g_1(\tau_b))^2} = \frac{e^{\pm \mu/N} f_2(\tau_a)g_2'(\tau_b)}{(1 + J^2 f_2(\tau_a)g_2(\tau_b))^2}
$$

(3.41)

where one of $\tau_{a,b}$ is fixed to be the value on a border between subregions, and subscripts 1 and 2 are used to distinguish the functions $f$ and $g$ on neighboring subregions (for example, 1 could refer to subregion $d$, 2 could refer to subregion $c$, and we choose minus sign in (3.41)). Let us fix $\tau_b$ as in (3.41), and then we can integrate $\tau_a$ to get

$$
\frac{g_1'(\tau_b)}{J^2 g_1(\tau_b)(1 + J^2 f_1(\tau_a)g_1(\tau_b))} = \frac{e^{\pm \mu/N} g_2'(\tau_b)}{J^2 g_2(\tau_b)(1 + J^2 f_2(\tau_a)g_2(\tau_b))} + c
$$

(3.42)

One can easily find the relation between $f_1(\tau_a)$ and $f_2(\tau_b)$ across the border: they are related to each other via an $SL(2)$ transformation that depends on the values of $g_{1,2}$ on the border. Note that this boundary condition does not give any information about how $g_1(\tau_b)$ is related to $g_2(\tau_b)$. Since we have a global $SL(2)$ symmetry, we can do a $SL(2)$ transformation for $f_2$ and $g_2$ such that $f_1 = f_2$. A similar analysis applies to other borders to fix $b$, $c$ and $d$ with same $f^\mu$ and $a$, $c$ and $e$ with same $g^\mu$ (see Fig. 4).

Note that now the symmetry lines are $\tau_a = \pm \tau_b$, across which we have

$$
G_{\mu}(\tau_a, \tau_b) = G_{-\mu}(\tau_b, \tau_a), \quad G_{\mu}(\tau_a, \tau_b) = G_{-\mu}(-\tau_b, -\tau_a)
$$

(3.43)

Together with the smoothness requirement, this strongly constrains the function choice in subregion $b$ (see Fig. 4). Suppose the function in $b$ is denoted as $(f^\mu_0, g^\mu_0)$. Then (3.43) implies that

$$
(f^\mu_0, g^\mu_0) \simeq (g_0^{-\mu}, f_0^{-\mu}), \quad (f^\mu_0, g^\mu_0) \simeq (g_0^{-\mu}, f_0^{-\mu})
$$

(3.44)

where $*$ denotes the flip $\tau \to -\tau$. It follows that $g^\mu_0$ must be a $SL(2)$ transform of $f_0^{-\mu}$. Let us assume $g^\mu_0 = \tilde{SL}_\mu(f^\mu_0)$ which obeys $(f^\mu_0, \tilde{SL}_\mu(f^\mu_0)) \simeq (\tilde{SL}_{-\mu}(f^\mu_0), f_0^{-\mu})$ due to the first symmetry in (3.43). When $\mu = 0$, we see from (3.36) that the gluing $\tilde{SL}$ reduces to the identity so that the solution is smooth.

Similarly, $f^\mu_0$ must be related to $f^\mu_0$ by an $SL(2)$ transformation, as $f^\mu_0 = sL_\mu(f^\mu_0)$, due to the second symmetry in (3.43) and this $SL(2)$ transformation should also be compatible with $\tilde{SL}_\mu$. This imposes a few constraints on both $SL(2)$ transformations. Such an analysis
Figure 4: The assignment of different \((f_i, g_i)\) functions to each region with all symmetry conditions satisfied in the large \(q\) case. We need to determine three functions \(f^\mu, g^\mu_1\) and \(g^\mu\) with twist boundary condition on the blue rectangle, and four \(SL(2)\) transformations \(\tilde{SL}_\mu, \overline{SL}_\mu, \overline{SL}_\mu\) and \(sl_\mu\).

can be applied to regions \(a\) and \(e\), in which each have only one symmetry. Taking all these symmetries in to account, we only need to determine three functions \(f^\mu, g^\mu_1\) and \(g^\mu\) with twist boundary condition on the blue rectangle in Fig. 4, and four \(SL(2)\) transformations \(\tilde{SL}_\mu, \overline{SL}_\mu, \overline{SL}_\mu\) and \(sl_\mu\).

The twist boundary conditions on the four blue segments in Fig. 4 are given as follows

\[
\begin{align*}
\tilde{SL}_\mu(f^\mu)(\tau_-) &= e^\mu g^\mu(\tau_-), \\
\overline{SL}_\mu(g^\mu_1)(\tau_\pm) &= e^\mu f^\mu(\tau_\pm), \\
\overline{SL}_\mu(g^\mu_1)(\tau_-) &= e^\mu f^\mu(\tau_-), \\
\overline{SL}_\mu(g^\mu_1)(\tau_-) &= e^\mu f^\mu(\tau_-)
\end{align*}
\]

where \(\tau_\pm \equiv \beta/4 \pm \epsilon\). We can use these equations to show that \(\tilde{SL}_\mu\) is completely determined by \(\tilde{SL}_\mu\). See Appendix A for more details.

Let us discuss the UV constraint, which requires that \(e^\sigma = 1\) when \(\tau_\alpha = \tau_\beta - \beta/2\). In general, this condition is surprisingly easy to satisfy. In the unshifted coordinate \(\tau_\alpha\), it means that

\[
\frac{f'(\tau)g'(\tau)}{(1 + J^2 f(\tau)g(\tau))^2} = 1
\]

Indeed, for arbitrary \(f\) and \(g\), we need only to choose \(\tau\) as the proper length in the space \((f, g) \in \mathbb{R}^2\) with metric

\[
d\tau^2 = \frac{df \, dg}{(1 + J^2 f(\tau)g(\tau))^2}
\]
Therefore, in principle we may expect infinitely many solutions for \((f^\mu, g_1^\mu, g_\mu)\) satisfying all of the conditions of our problem. Indeed, this is because the large \(q\) equation of motion (3.23) is too loose. The constructive approach would require working to the next order in \(1/q\), which should lift the flat direction of solutions.

However, to get find any solution analytically is not easy. For example, it is not clear that after redefining \(\tau\) according to UV requirement, the functions in region \(a\) will be still of the form \((\tilde{SL}_\mu(g_{1x}^{-\mu}), g_1^\mu)\), namely that the first component is related to the second one via a reflection and \(SL(2)\). In order to find a reasonably simple solution, we make further assumptions:

\[
f^\mu = f, \quad g_1^\mu = G(f) \equiv \frac{A_\mu + B_\mu f}{C_\mu + D_\mu f}, \quad \tilde{SL}_\mu = I
\]

which also implies that \(\tilde{SL}_\mu = I\). The first assumption \(f^\mu = f\) is quite strong, but it is a good candidate to satisfy the strong symmetry constraints in subregion \(b\). The second assumption is inspired by (3.15) where moving across \(e^{i\mu V}\) is a \(SL(2)\) transformation for \(\psi\).

An important consistency criterion on the solution is that when it is continued to Lorentz signature and the limit \(\epsilon \to 0\) is taken, it should obey causality. In other words, the correlation functions in the past of the interaction \(e^{i\mu V}\) must be the original ones of the thermodfield double state in the decoupled system. We will see later that our solution has this property. For example in the region \(b\), with our ansatz \(\langle \psi(t') e^{igV} e^{-igV} \psi(t) \rangle\) is the original translation invariant two point function. However in region \(d\), only after taking \(\epsilon \to 0\) can one see that the Lorentzian solution obeys causality.

With this ansatz, solving for \((f, g_1, g_\mu)\) in all subregions is straightforward. We leave the details to Appendix A and only describe the result here. Taking \(\tau_+ = \tau_- = \beta/4\) and shifting \(\tau_a\) back \(\tau_a \to \tau_a - \beta/2\), the solutions of \(e^\sigma\) in each subregion are as follows:

\[
[e^\sigma]_{(a)} = \frac{e^{-2\mu/N} \omega^2}{J^2} \left[ \cos \omega (\tau_{ab} - \frac{\beta}{2}) + \frac{(e^{-\mu/N} - 1)}{\cos \omega \beta/2} \cos \omega \tau_{ab} \right. \\
+ \left. \frac{(e^{-\mu/N} - 1)^2 \sin \omega \beta/2}{\cos^2 \omega \beta/2} \cos \omega (\tau_a - \frac{\beta}{4}) \sin \omega (\tau_b - \frac{\beta}{4}) \right]^{-2}
\]

\[
[e^\sigma]_{(b)} = [e^\sigma]_{(c)} = [e^\sigma]_{(d)} = \frac{\omega^2}{J^2 \cos^2 \omega (\tau_{ab} - \frac{\beta}{2})}
\]

\[
[e^\sigma]_{(c)} = \frac{e^{-\mu/N} \omega^2}{J^2 \left( \cos \omega (\tau_{ab} - \frac{\beta}{2}) + \frac{(e^{-\mu/N} - 1)}{\cos \omega \beta/2} \sin \omega (\tau_a - \frac{\beta}{4}) \sin \omega (\tau_b - \frac{\beta}{4}) \right)^2}
\]

It is interesting that the solution in subregion \(c\) has the same form as that in [27].

4 Effectiveness of protocol

In order to check the mutual information \(I_{RT}\) after performing the protocol, we need to evaluate correlation functions in Lorentz signature. The Lorentzian correlation functions are analytic continuations of \(G_{\mu}\). For example, the OTOC \(\langle U^l \psi_1^l(t) U\psi_1^l(t) \rangle\) is equal to

\[
\lim_{\epsilon \to 0} G_{\mu\nu}(\beta/4 + it, (\beta/4 - \epsilon)_- + it)
\]
4.1 Lorentzian correlation function

To find the density matrix \( \rho_{ij} \), we need to calculate a few OTOCs. We first consider

\[
\mathcal{K}(t, t') = \left\langle \{ \psi_i(-t'), U^\dagger \psi_i(t) U \} \right\rangle = \left\langle \psi_i(-t') U^\dagger \psi_i(t) U \right\rangle + \left\langle U^\dagger \psi_i(t) U \psi_i(-t') \right\rangle \tag{4.2}
\]

Comparing with the definition of \( \mathcal{G}_\mu \), we can easily find that

\[
\mathcal{K}(t, t') = -i \lim_{\epsilon \to 0} \left[ \mathcal{G}_{\mu}(it' + \beta(1/4 + \epsilon)_+, 3\beta/4 - it) + \mathcal{G}_{\mu}(3\beta/4 - it, -it' + \beta(1/4 - \epsilon)_-) \right] = \frac{i}{2} \left( \frac{e^{-i\nu/(Nq)} \omega^{2/q}}{J^{2/q} \left[ \cosh \omega \Delta t - \frac{J(e^{-i\omega/(N-1)})}{\omega} \sinh \omega(t - i\beta/2) \sinh \omega t'} \right]^{2/q} - h.c. \right) \tag{4.3}
\]

where we used symmetries from Sec. 3.1.1 to express \( \mathcal{G}_\mu \) in the fundamental domain and in the last line \( \Delta t = t' - t \).

There is another type of OTOC involved in \( \rho_{ij} \), namely \( \langle \psi^\dagger \psi^\dagger U^\dagger \psi \psi^2 U \rangle \). One can follow a similar procedure as in the calculation of \( \mathcal{G} \) to derive the resulting twist boundary condition for four point correlation functions

\[
\hat{\mathcal{G}}(\tau_a, \tau_b; \tau_c, \tau_d) = \frac{\left| \left\langle I e^{-\beta H/2} \mathcal{T} [e^{-\mu V(\beta/4 + \epsilon)} e^{\mu V(\beta/4 - \epsilon)} \psi^1(\tau_a) \psi^1(\tau_b) \psi^2(\tau_c) \psi^2(\tau_d) \right\rangle \right|}{\left| \left\langle I e^{-\beta H/2} e^{-\mu V(\beta/4 + \epsilon)} e^{\mu V(\beta/4 - \epsilon)} \right\rangle \right|} \operatorname{sgn}(\bar{\tau}_a, \bar{\tau}_b, \bar{\tau}_c, \bar{\tau}_d) \tag{4.4}
\]

where \( \operatorname{sgn}(\bar{\tau}_a, \bar{\tau}_b, \bar{\tau}_c, \bar{\tau}_d) = 1 \) for \( \bar{\tau}_a > \bar{\tau}_b > \bar{\tau}_c > \bar{\tau}_d \) and the sign flips for every permutation of the order. It is very straightforward to see that for fixed \( \tau_c \) and \( \tau_d \), the correlator as a function of \( \tau_a \) and \( \tau_b \) obeys the same twist boundary condition when crossing \( e^{\pm \mu V} \) as before. The same applies to the boundary condition for \( \tau_c \) and \( \tau_d \) with \( \tau_a \) and \( \tau_b \) fixed. Therefore, we can understand \( \hat{\mathcal{G}} \) as a four point function \( \langle I e^{-\beta H/2} \mathcal{T} [\psi^1(\tau_a) \psi^1(\tau_b) \psi^2(\tau_c) \psi^2(\tau_d) \right\rangle \) with two copies of the twist boundary conditions. On the other hand, due to \( SO(N) \) global symmetry and large \( N \) limit

\[
\left| \left\langle I e^{-\beta H/2} \mathcal{T} [G(\tau_a, \tau_b) G(\tau_c, \tau_d) \right\rangle \right| = \left| \left\langle I e^{-\beta H/2} \mathcal{T} [\psi^1(\tau_a) \psi^1(\tau_b) \psi^2(\tau_c) \psi^2(\tau_d) \right\rangle \right| + O(N^{-1}) \tag{4.5}
\]

where we suppressed the insertion of \( e^{\pm \mu V} \) for notational simplicity. In the large \( N \) limit, the leading order contribution to \( \langle I e^{-\beta H/2} \mathcal{T} [G(\tau_a, \tau_b) G(\tau_c, \tau_d) \right\rangle \) is disconnected, namely the product of two correlation functions \( G(\tau_a, \tau_b) G(\tau_c, \tau_d) \).

Now we are readily write down the contribution to \( \rho_{ij} \) from this type of OTOC. In \( \rho_{11} \), we have

\[
\approx \frac{1}{N^2} \sum_{i,j} \left\langle \{ \psi^1_i(-t'), [\psi^2_i(-t'), U^\dagger \psi^1_j(t) \psi^2_j(t) U] \} \right\rangle \\
\approx - \left\langle \{ \psi^1_i(-t'), U^\dagger \psi^1_j(t) U \} \right\rangle \left\langle \{ \psi^1_i(-t'), U^\dagger \psi^1_j(t) U \} \right\rangle \\
\approx - \mathcal{K}(t, t')^2 \tag{4.6}
\]
where in second line we used the identity (4.5) and the fact that \( \psi_r^1(t)\psi_r^1(t) = 1/2 \), and in third line we used factorization at large \( N \). Similarly, the correlation function appearing in \( \rho_{14} \) is given by

\[
\left\langle \{ \psi_l^2(-t'), \psi_l^1(-t') U^\dagger \psi_r^2(t) U \psi_r^1(-t') \} \right\rangle \approx -\frac{1}{2} \mathcal{K}(t,t') \tag{4.7}
\]

From these results, we obtain

\[
\rho_{11} = \frac{1}{2} (1 + \mathcal{K}(t,t')^2), \quad \rho_{14} = \mathcal{K}(t,t') \tag{4.8}
\]

and other \( \rho_{ij} \) via (2.64) to (2.66). From (4.3) we know that \( \mathcal{K} \) (short for \( \mathcal{K}(t,t') \)) is a real valued function, which is consistent with the fact that \( \rho \) is hermitian. It follows that the mutual information between \( R \) and \( T \) is

\[
I_{RT} = \frac{1}{4} \left[ (\mathcal{K} - 1)^2 \log(\mathcal{K} - 1)^2 + (\mathcal{K} + 1)^2 \log(\mathcal{K} + 1)^2 + 2(1 - \mathcal{K}^2) \log(1 - \mathcal{K}^2) \right] \tag{4.9}
\]

We plot the dependence of \( \mathcal{K} \) in Fig. 5. We see that \( I_{RT} \) is close to maximal when \( \mathcal{K} \) approaches to \( \pm 1 \).

### 4.2 Semiclassical limit

Our analysis relied on the leading \( 1/N \) description of the SYK model in terms of classical \( G \) and \( \Sigma \) collective fields. The interaction (2.50) coupled all \( N \) fermions \( \psi_l^1 \) with \( \psi_r^1 \) with a coefficient which we took to scale as \( \mu/(qN) \) for fixed \( \mu \). We further specialized to the large \( q \) limit, although \( q \ll N \). In other words, at each order in the \( 1/q \) expansion we kept only the leading effects in \( 1/N \).

Due to the instantaneous nature of the interaction, we treated it exactly in terms of the fundamental Majoranas, which resulted in particular twist boundary conditions for the collective fields across the interaction time. In this way, the \( 1/N \) effect arising from the Schwarzian effective action that dominates at large \( \beta J \) is automatically resummed into a closed form by the full solution with twist boundary conditions, as in [27]. Moreover, our analysis includes effects beyond the Schwarzian approximation, which are important.
for understanding how the operations involving the fundamental Majoranas glue into the gravitational dual near the boundary, as discussed below. We will see that those “stringy” corrections are crucial for regulating the pole in the gravity transmission amplitude in the probe approximation and are thus very important for finding the effectiveness of the teleportation protocol. It will not require going to higher orders in the $1/N$ expansion.

The scrambling time required for traversability is associated to the limit of large $N$ with $e^{\omega(t+t')} / N$ fixed. Then $\mathcal{K}$ becomes

$$\mathcal{K} = -\Im \left( \frac{\omega^{2/q}}{\mathcal{J}^{2/q} \left[ \cosh \omega \Delta t + i \frac{\mu}{4\Delta N} e^{\omega(t+t')} e^{-i\omega \beta/2} \right]^{2/q}} \right) \quad (4.10)$$

In the strong coupling or low temperature limit, $\beta \mathcal{J} \gg 1$, the frequency becomes

$$\omega = \mathcal{J} \cos \omega \beta / 2 \implies \omega = \frac{\pi}{\beta} - \frac{2\pi}{\beta^2 \mathcal{J}} + O(1/\mathcal{J}^2) \quad (4.11)$$

Plugging this into $\mathcal{K}$, we get

$$\mathcal{K} \approx -\Im \left( \left[ \frac{\pi/(\beta \mathcal{J})}{\cosh \pi \Delta t / \beta + \frac{\mu}{4\Delta N} e^{\pi(t+t')/\beta} e^{i\pi/(\beta \mathcal{J})}} \right]^{2/q} \right) \quad (4.12)$$

which has the maximal Lyapunov exponent of $2\pi / \beta$ [30].

A quick conclusion from (4.12) is that ignoring the numerator, if $\mathcal{J}, N / \mathcal{J} \to \infty$, a negative $\mu$ will lead to a pole for large enough $t + t'$. To compare with gravity result explicitly, we can define

$$g = -\mu, \quad \Delta = 1/q, \quad G_N = \frac{4\Delta \beta \mathcal{J}}{\pi \Delta N} \quad (4.13)$$

and the first term in (4.12) now becomes

$$\left( \frac{\pi}{\beta \mathcal{J}} \right)^{2\Delta} \frac{1}{\left( \cosh \pi \Delta t / \beta - \frac{\Delta g}{2 \Delta N} G_N e^{\pi(t+t')/\beta} \right)^{2\Delta}} \quad (4.14)$$

which exactly matches with the semiclassical gravity result of [2] (associated to traversal of a probe signal, ignoring its backreaction). Such a pole indicates that the bulk geometry is a traversable wormhole in which there exist timelike geodesics connecting the $l$ system at $-t'$ with the $r$ system at $t$. The negative sign required for $\mu$ is also consistent with [16], in which a large coupling $\mu$ that remains on for all time will result in thermofield double state becoming an eternal traversable wormhole.

An actual pole in the result would violate unitarity, since the fermion number operator must have an expectation value between 0 and 1. This is consistent with our result, as due to the existence of numerator, the value of $\mathcal{K}$ does not blow up. This comes from the UV physics of SYK model and cannot be seen in the low energy gravity theory. In the large $\mathcal{J}$ limit, the numerator $1/(\beta \mathcal{J})$ and the exponential $e^{i\pi/(\beta \mathcal{J})}$ perfectly balance to give a finite maximal value of $|\mathcal{K}|$. 

This $1/(\beta J)$ effect comes from a correction to maximal Lyapunov exponent, thus we may refer it as a “stringy” effect in the putative dual bulk theory of SYK. For evaluating the effectiveness of the teleportation protocol, this stringy effect is crucial, as it determines the actual maximal value of $|K|$. The nontrivial exponential and the $1/\beta J$ correction to Lyapunov exponent are also related to the near coherent scrambling discussed in [31].

At weak coupling or high temperature, $\beta J \ll 1$, the frequency is given by $\omega \approx J$, and $K$ becomes

$$K \approx -\Im \left( \left[ \frac{1}{\cosh J \Delta t + i\mu} \right]^{2/q} \right) \tag{4.15}$$

As $t + t'$ grows, $K$ also has a peak, but it is not as high and sharp as in the low temperature case. In particular, the denominator then never leads to a pole. This is unsurprising because at high temperatures, the full stringy dual of the SYK model is unknown, and is certainly not semi-classical gravity. It is also worth noting that the Lyapunov exponent now is $2J$, as expected [32]. In this paper we are mainly interested in the low temperature limit and leave discussion of high temperature to Sec. 5.1.

To see the location and value of the peak of $K$ in (4.12), it is useful to define parameters

$$a \equiv \pi/(\beta J), \quad x \equiv -\frac{\mu}{4N} e^{2\pi t/\beta}, \quad y \equiv -\frac{\mu}{4N} e^{2\pi t'/\beta} \tag{4.16}$$

in terms of which (4.12) can be written as

$$K = -\left[ \frac{4a^4xy}{4x^2y^2 + a^2(x+y)^2 - 4axy(x+y)\cos a} \right]^{1/q} \times \sin \left[ \frac{2}{q} \arccos \frac{a(x+y) - 2xy\cos a}{\sqrt{4x^2y^2 + a^2(x+y)^2 - 4axy(x+y)\cos a}} \right] \tag{4.17}$$

To find the minimal value of $K$ (note that $K < 0$), we extremize it with respect to $x$ and $y$. Expanding in small $a$, the solution is

$$x = y = a + a^2 \cot \frac{2\pi}{q + 2} + O(a^3) \tag{4.18}$$

which defines a time $t = t' = t_0$ by (4.16). Using this solution, we find that the minimal value of $K$ around $a \approx 0$ is achieved when $J \rightarrow \infty$, $a \rightarrow 0$. In this limit, the minimal value of $K$ is

$$K_{\text{min}} = -\left[ \sin \frac{2\pi}{q + 2} \right]^{1+2/q} \tag{4.19}$$

From this expression and (4.9), we see that $|K_{\text{min}}|$ and $\max(I_{RT})$ decrease as $q$ becomes larger. This is reasonable as $K$ is the imaginary part of the first term in (4.12) and $q$
controls its phase, which decreases as $1/q$. For large $q$ the scaling is
\[ K_{\text{min}} \sim -2\pi/q, \quad \frac{\max(I_{RT})}{2\log 2} \sim \frac{2\pi^2}{q^2 \log 2} \] (4.20)

We present the maximal values of $I_{RT}$ for a several values of $q$ in Table 1.

With this protocol, the large $q$ limit does not lead to perfect teleportation. However, the mutual information does grow in time from exponentially small values at early times to an order 1 number after the scrambling time. By examining the density matrix in more detail one can determine whether quantum entanglement between $R$ and $T$ is generated, or if only classical correlation appears. In Sec. 5.4 we show that the resulting density matrix is inseparable. Thus we could then imagine taking an $O(1)$ number of copies of SYK model and performing entanglement distillation [33–35], which would increase the fidelity of teleportation.

It turns out that there is a more elegant way of improving the protocol. In Sec. 4.3 we shown that applying the initial SWAP operation to a product of order $q$ fermions achieves almost fidelity of teleportation.

We plot various features of the time dependence of the transmitted signal in Fig. 6. The final signal, $K$, is plotted as a function of time, $t$, for several different initial injection times $-t'$ into the left SYK system in Fig. 6. Characterizing the arrival time of the signal by the location of peak, we see there are two distinct cases. If the injection time is not sufficiently early (in Fig. 6a), the peaks move to later times when we have earlier injection. In other words, the time ordering of the signal is inverted. On the other hand, if the injection time is early enough (in Fig. 6b), the peaks move to earlier times when we have earlier injection. That means that the time ordering of the signal is preserved.

The latter behavior is what is expected for travel through a traversable wormhole in semiclassical gravity. Denote the transition time between the two behaviors as $t' = t_s$. From Fig. 6a and Fig. 6b, it is clear that the signal significantly strengthens when $t' > t_s$. The range $t' > t_s$ should be thought of as the semiclassically traversable regime. Outside of this semiclassical regime, the time ordering is reversed due to the pattern of entanglement in the thermofield double state, which is consistent with the analysis of [26].

We can also find the peak arrival time, $t$ for which $\partial_t K = 0$, as a function of the injection time $-t'$. The arrival time $t(t')$ achieves its maximum when $t' = t_s$. As an example, for large $J$ we plot this function in terms of exponentiated variables $x(y)$ for various values of $q$ in Fig. 6c. It is clear that there exists a transition point $t_s$ where the time ordering of the signal flips. For small $a$ (large $J$), this transition point in terms of the variables $x$ and $y$ can be calculated as a series in $a$:

\[
x_s = \sqrt{\frac{q + 2}{q}} \frac{\sin^2 q\theta/2}{\sin \theta} + O(a),
\]
\[
y_s = \frac{1}{2}a - \frac{a^2}{2\sqrt{q(q + 2)} \sin \theta} + O(a^3)
\]
(4.21)

where $\theta$ is the first positive solution to the transcendental equation

\[
\tan \frac{q\theta}{2} = \frac{\sqrt{q} \sin \theta}{\sqrt{q + 2} - \sqrt{q} \cos \theta}
\] (4.22)
Figure 6: The plot of \( \mathcal{K} \) as a function of arrival time \( t \) for different injection time \(-t'\) around transition time \(-t_s\). Blue, yellow, green and red correspond to increasing \( t' \) (earlier injection). (a) shows \( t' < t_s \) where peaks move to right and have opposite ordering of signal, and (b) shows \( t' > t_s \), where peaks move to left and have same ordering of signal. (c) shows the peak location \( x(y) \) for \( q = 4, 8, 12 \) (blue, yellow and green). It is clear that there exists transition point \( t_s \) at which the time ordering of signal flips. The dashed line is \( y = a/2 \).

whose solution at large \( q \) is \( \theta \approx \frac{2.331}{q} \). The transition time \( t_s \) is defined in terms of \( y_s \) by

\[
t_s \equiv T_0 + \frac{\beta}{2\pi} \log y_s, \quad T_0 = \frac{\beta}{2\pi} \log \frac{4N}{-\mu}
\]

which is the latest injection time \(-t' = -t_s\) for which the signal preserves time ordering. Similarly, \( t_{\text{max}} \) is defined via \( x_s \) by

\[
t_{\text{max}} \equiv T_0 + \frac{\beta}{2\pi} \log x_s
\]

which is the latest arrival time \( t = t_{\text{max}} \) after which \( \mathcal{K} \) has no peak.

Comparing (4.18) with (4.21), we find that the minimal value of \( \mathcal{K} \) occurs with injection time \(-t_0\), which is before the transition time. This matches our observation in Fig. 6, and \( \mathcal{K}_{\text{min}} \) in (4.19) is in the semiclassical regime. Moreover, we can plug the value of transition time (4.21) into \( \mathcal{K} \) and find \( \mathcal{K} \sim a^{1/q} \) in the small \( a \) limit. This means that little signal gets through if injected at or after the transition time, in the low temperature limit. Note that \( a \sim 1/\beta J \) controls “stringy” effects in the bulk. Physically, injections later than
transition time with inverse timing ordering classically do not get through the wormhole at all and would die in the singularity. However, injections close to the transition time travel close enough to the (ultimate) horizon that fluctuations in the effective metric determine whether they get through. Such fluctuations are due to “stringy” effect as indicated by the $|K|$ peak value being suppressed by $(\beta J)^{-1/q}$.

There is another time scale appears Fig. 6c in the limit $y \to \infty$, so the qubit is injected very early. It corresponds to the lower bound $x_{\text{min}}$ of $x$ that remains in the semiclassical regime. we calculate this as a series in $a$ by taking the equation $\partial_t K = 0$ in the $t' \to \infty$ limit

$$x_b = \frac{1}{2} a + \frac{1}{2} a^2 \cot \frac{2\pi}{q+2} + O(a^3)$$  \hspace{1cm} (4.25)

This defines the earliest semiclassical arrival time

$$t_{\text{min}} = T_0 + \frac{\beta}{2\pi} \log x_b$$  \hspace{1cm} (4.26)

The physical meaning of $t_{\text{min}}$ is obvious. Any signal arriving semiclassically via the traversable wormhole cannot arrive earlier than this time. It is reasonable to define the apparent duration $d$ of the throat of the traversable wormhole, as measured in boundary time on the right, by

$$d = t_{\text{max}} - t_{\text{min}} \approx \frac{\beta}{2\pi} \log \beta J$$  \hspace{1cm} (4.27)

It is interesting that the duration of the wormhole does not depend on $\mu$ and becomes divergent in the large $J$ limit. These time scales and the two regimes of time orderings of the signal are shown in Fig. 7.

After the peak, Fig. 6a and Fig. 6b show that $K$ has an exponential decay. This decay rate is easily seen from (4.12)

$$K \sim e^{-\Delta(2\pi t/\beta)} \text{ for } t \text{ large}$$  \hspace{1cm} (4.28)

where $\Delta = 1/q$ is the conformal weight of the Majorana fermion $\psi$. Thus the signal experiences a thermalization process after transmission to the $r$ system.

We make one final consistency check of our solution in the large $N$ limit. In (3.52), if we take $\tau_a \to 3\beta/4 - it'$ and $\tau_b \to \beta/4 + it$, we get

$$e^\sigma = \frac{J^2}{\omega^2} \left[ \cosh \omega \Delta t - \frac{i\mu}{N} (\cosh \omega \Delta t + i \tan \omega \beta/2 \sinh \omega \Delta t) \right. $$

$$-\frac{\mu^2 \tan \omega \beta/2}{N^2} \left( i \cosh \omega t' - \tan \omega \beta/2 \sinh \omega t' \right) \sinh \omega t \right]^{-2}$$  \hspace{1cm} (4.29)

which corresponds to the real correlation function

$$\langle tfd| \hat{U}^\dagger \psi_r(t') \psi_l(t) \hat{U} | tfd \rangle$$  \hspace{1cm} (4.30)

One can see that the denominator in (4.29) is real when $\Delta t$ and $e^{\omega(t+t')/N}$ are order 1, so that it simply reduces to the first term at leading order in the $1/N$ expansion. The imaginary part that appears at higher order cannot be trusted, as then loop corrections must also be included.
Figure 7: Three time scales of $\mathcal{K}$. We define the arrival time as the peak of $\mathcal{K}$. The signal emitted from $-t_s$ arrives at maximal time $t_{\text{max}}$ and that from $-\infty$ arrives at minimal time $t_{\text{min}}$. We define $t' > t_s$ as semiclassical regime because the ordering of signal is preserved (solid orange arrow). For $t' < t_s$, the ordering of signal is reversed (dashed orange arrow).

4.3 Improved protocol with multiple fermion SWAP

We found in (4.19) that $|\mathcal{K}_{\text{min}}|$ monotonically decreases with increasing $q > 2$. It is natural to expect that by encoding the teleported qubit in multiple fermions, the fidelity of the protocol can be improved. Noting that the $q$ dependence of the exponent in (4.12) comes from the $1/q$ conformal weight of $\psi$, we will consider making use of heavier operators made out of a product of several fermions.

To be more precise, we consider the following operators in each SYK system, where $p$ is an odd number.

\[
\Psi_{1,l,r} = 2^{(p-1)/2} \psi_{1,l,r}^3 \psi_{2,l,r} \psi_{2,p+1,l,r}, \quad \Psi_{2,l,r} = 2^{(p-1)/2} \psi_{2,l,r}^2 \psi_{2,p} \psi_{2,l,r}^4 \psi_{2,p+1,l,r} \tag{4.31}
\]

which satisfy

\[
\{ \Psi_i^a, \Psi_j^b \} = \delta_{ij} \delta_{ab}, \quad i, j = 1, 2, \quad a, b = l, r \tag{4.32}
\]

Therefore, we can use $\Psi_i$ to construct Dirac fermions $\chi$ and $\chi^\dagger$ as in Sec. 2.1

\[
\chi_{l,r} = \frac{1}{\sqrt{2}} (\Psi_{l,r}^1 + i \Psi_{l,r}^2), \quad \chi_{l,r}^\dagger = \frac{1}{\sqrt{2}} (\Psi_{l,r}^1 - i \Psi_{l,r}^2) \tag{4.33}
\]

which implies $\{ \chi_{l,r}, \chi_{l,r}^\dagger \} = 1$. As the $\Psi_i$ obey exactly the same algebra as a single Majorana fermion when acting on themselves, the density matrix elements are the same as (2.64)-(2.66) with the replacement of $\psi$ by $\Psi$.

We take $p$ to be a fixed number that does not scale with $N$, so that the correlation functions involving $\Psi_i$ will factorize into products of correlations functions of the component Majorana fermions (with the usual twist boundary conditions for each component). It follows that the mutual information formula (4.9) for $I_{RT}$ still holds but with $\mathcal{K} \to \mathcal{K}_p$ given by

\[
\mathcal{K}_p = \left\langle \{ \Psi_i(-t'), \mathcal{U}^\dagger \Psi_r(t) \mathcal{U} \} \right\rangle = 2^{p-1} \left[ \left\langle \psi_i(-t') \mathcal{U}^\dagger \psi_r(t) \mathcal{U} \right\rangle^p + \left\langle \mathcal{U}^\dagger \psi_r(t) \mathcal{U} \psi_i(-t') \right\rangle^p \right] \tag{4.34}
\]
where we omitted the superscript of $\Psi$. For low temperatures, its value is

$$K_p \approx i^{p+1} \Im \left( \frac{\pi/(\beta J)}{\cosh \pi \Delta t/\beta + J \mu \beta 4 \pi N e^{\pi/2} / \rho e^{i\pi/(3J)}} \right)^{2p/q}$$  \hspace{1cm} (4.36)$$

where $i^p = \pm i$ is pure imaginary as $p$ is an odd number. All of our previous analysis applies with a rescaled $q \rightarrow q/p$. This is reasonable as $\Psi^i$ consists of $p$ Majorana fermions and thus has conformal weight $p/q$.

We are interested in the $p$ value that leads to the highest fidelity teleportation. Odd $p$ guarantees that (4.35) is pure imaginary, so this means maximizing $|K_p|$. Using (4.19) we have

$$|K_p|_{\text{max}} = \left[ \sin \frac{2\pi}{q/p + 2} \right]^{1+2p/q}$$  \hspace{1cm} (4.37)$$

where it reaches the maximum value of 1 at $p/q = 2$. This is perfect fidelity teleportation. However, as we assumed that $q \in 4\mathbb{Z}$ and $p$ is odd, we can only choose $p = q/2 \pm 1$. Of these, $p = q/2 + 1$ will give the larger $|K_p|_{\text{max}}$. Therefore the improved protocol gives

$$|\mathcal{K}|_{\text{max}} \equiv |K_{q/2+1}|_{\text{max}} = \left[ \sin \frac{(q+2)\pi}{2(q+1)} \right]^{2+2/q}$$  \hspace{1cm} (4.38)$$

which approaches 1 when $q \rightarrow \infty$. Expanding at large $q$, we can see how close the protocol is to perfect fidelity

$$|\mathcal{K}|_{\text{max}} \approx 1 - \frac{\pi^2}{4q^2} \cdot \frac{\max(I_{RT})}{2 \log 2} \approx 1 - \frac{\pi^2}{4 \log 2} \cdot \frac{\log q}{q^2}$$  \hspace{1cm} (4.39)$$

For high temperatures, the effect of using multiple fermions is similarly a replacement $q \rightarrow q/p$ in the previous result (4.15). This leads to a maximal value of $|\mathcal{K}|$ given by

$$|\mathcal{K}|_{\text{max}} = \left[ \sin \frac{\pi}{q/p + 2} \right]^{1+2p/q}$$  \hspace{1cm} (4.40)$$

which approaches to 1 as $p \rightarrow \infty$. We expand it at large $p$ and find

$$|\mathcal{K}|_{\text{max}} \approx 1 - \frac{\pi^2 q}{16p} \cdot \frac{\max(I_{RT})}{2 \log 2} \approx 1 - \frac{\pi^2}{32 \log 2} \cdot \frac{q \log p/q}{p}$$  \hspace{1cm} (4.41)$$

With this improved protocol, we can encode our qubit into the composite fermion field of $q/2 + 1$ Majorana fermions in the low temperature regime or into $p$ Majorana fermions with $p \gg q$ in the high temperature regime to achieve almost perfect teleportation. The first case has a dual interpretation of a particle passing through the traversable wormhole. The high temperature limit of the SYK model must have a very stringy bulk, and it would be interesting to understand the interpretation of our result in that regime.
5 Discussion

5.1 Interference regime

When an excitation is sent into the wormhole at very early times, its collision with the negative energy squeezed state is highly trans-Planckian and the backreaction is large. It was shown in [2, 26] that nevertheless the left-right correlation function $K$ remains nonzero due to an interference effect. We now examine whether this interference effect can lead to teleportation with our protocol. Note that the above large $q$ solution is related to semi-classical gravity plus “stringy” effects and does not include the interference regime, which goes beyond the leading $1/N$ contributions. Therefore, we have to discuss it separately.

The interference effect relies on the facts that time-ordered correlation functions factorize and out-of-time-ordered correlation functions vanish due to the nature of quantum chaos. Basically, we have

$$e^{i\mu V} |\text{tfd}\rangle \approx e^{i\mu \langle V \rangle} |\text{tfd}\rangle,$$

$$e^{i\mu V} \psi_{l,r}^1 \cdots \psi_{l,r}^s |\text{tfd}\rangle \approx \psi_{l,r}^1 \cdots \psi_{l,r}^s |\text{tfd}\rangle$$

(5.1)

where $\langle V \rangle = i \langle \psi_l(0) \psi_r(0) \rangle / q$ is an order 1 number. Note that the large $q$ solution above does not capture the interference regime because $K$ vanishes for large $t$ and $t'$ in (4.3) whereas the interference effect implies that it should be $2 \Re(e^{i\mu \langle V \rangle} \langle \psi_l(-t') \psi_r(t) \rangle)$. Using (5.1) we find that

$$\langle \{\psi_1^l, [\psi_2^l, U\psi_r^1 U]\} \rangle \rightarrow 4 \sin^2 \frac{\mu \langle V \rangle}{2} \langle \psi_1^l \psi_r^1 \rangle^2$$

(5.2)

$$\langle \{\psi_1^l, U\psi_r^1 U\} \rangle \rightarrow 2i \sin \mu \langle V \rangle \langle \psi_1^l \psi_r^1 \rangle$$

(5.3)

$$\langle \{\psi_2^l, \psi_1^l U^\dagger \psi_r^1 U \psi_1^l \} \rangle \rightarrow 0$$

(5.4)

which leads to

$$\rho_{11} = \frac{1}{2} - 2 \sin^2 \frac{\mu \langle V \rangle}{2} \langle \psi_1^l \psi_r^1 \rangle^2$$

(5.5)

$$|\rho_{14}| = \sin \mu \langle V \rangle \langle \psi_1^l \psi_r^1 \rangle$$

(5.6)

where $\langle \cdot \rangle$ is short for $\langle \text{tfd} | \cdot | \text{tfd} \rangle$. Note that $\langle \psi_1^l \psi_r^1 \rangle$ is pure imaginary because the correlation function between $\psi_l$ and $i\psi_r$ is real. Moreover, $| \langle \psi_1^l \psi_r^1 \rangle |$ is bounded by 1/2 via Schwarzian inequality. For different values of $| \langle \psi_1^l \psi_r^1 \rangle |$, we plot $I_{RT}$ as a function of $\mu \langle V \rangle$ in Fig. 8.

In the low temperature limit, $| \langle \psi_1^l \psi_r^1 \rangle | \sim \langle V \rangle$ scales as $\frac{1}{2}(\pi/\beta \mathcal{J})^{2/q}$ which is a small number (much smaller than order 1). From Fig. 8 we see that $I_{RT}$ is quite small and not sufficient for successful teleportation. More precisely, one can show that

$$I_{RT} \sim (\beta \mathcal{J})^{-8/q}$$

(5.7)

On the other hand, in the high temperature limit, $\langle \psi_1^l \psi_r^1 \rangle \rightarrow i/2$, which leads to an order 1 magnitude for $I_{RT}$. In this case, $I_{RT}$ is bounded by $\log 2$. Although the mutual information does not reach maximality, for appropriate choices of $\mu$ some quantum information is teleported via the interference effect, as we will discuss in Sec. 5.4.
Figure 8: Mutual information $I_{RT}$ as a function of $\mu \langle V \rangle$ for different $|\langle \psi^l_1 \psi^r_1 \rangle|$. Blue, yellow, green and red represent for $|\langle \psi^l_1 \psi^r_1 \rangle| = 0.2, 0.3, 0.4, 0.5$ respectively.

5.2 Partial coupling

In this section we consider a simple generalization of the protocol in which only a fraction of the Majorana fermions are coupled in the interaction Hamiltonian. This is also required for the coupling being interpreted as a classical channel as discussed in Sec. 2.1. It is particularly interesting to consider measuring the correlation function of fermions that do not appear in the interaction. The quantum chaotic nature of the SYK Hamiltonian implies that there need be no relation between the fermions that are coupled with the fermions that are transmitted, as expected in the gravity description.

We consider coupling only the first $\alpha N$ Majorana fermions

$$H_{int} = -\mu \tilde{V} = -\frac{i\mu}{q\alpha N} \sum_{j=1}^{\alpha N} \psi^l_j \psi^r_j$$

and we calculate the correlation function for the last $(1 - \alpha)N$ Majorana fermions

$$\sum_j^\prime \left\langle I | e^{-\beta H/2} \mathcal{T} [e^{-\mu \tilde{V} (\beta/4 + \epsilon)} e^{\mu \tilde{V} (\beta/4 - \epsilon)} \psi^j (\tau_a) \psi^j (\tau_b)] | I \right\rangle$$

where $\sum^\prime$ means summing $j$ from $\alpha N + 1$ to $N$. It is clear that $\psi^j$ can freely move across $\tilde{V}$ for $j = \alpha N + 1, \cdots, N$, so they do not obey a twisted boundary condition. One might naively conclude that such correlation functions do not have any of the nontrivial features of $G_\mu$ in the various subregions in Fig. 4 that we found before, in particular that there would be no exponential growth in subregion $c$ after continuation to Lorentz signature.

However, this expectation is incorrect. Indeed, from the general analysis of the SYK model, the low energy effective action is the Schwarzian that universally couples to all fermions [15]. Thus the OTOC between different species of fermions should have exponential growth at order $1/N$. Moreover, traversable wormholes should exist for generic coupled operators based on analysis of both the gravity [1] and CFT [26] sides.

---

Here we assume $\alpha N$ is an integer of order $N$. 
The resolution is that we need to treat the effective action (2.47) more carefully. As we separated the fermions into two groups, we need to define two different \( \Sigma \) and \( G \) fields
\[
G_1(\tau, \tau') = \frac{1}{\alpha N} \sum_{i=1}^{\alpha N} \psi_i(\tau) \psi_i(\tau') \tag{5.10}
\]
\[
G_2(\tau, \tau') = \frac{1}{(1 - \alpha)N} \sum_{i=\alpha N+1}^{N} \psi_i(\tau) \psi_i(\tau') \tag{5.11}
\]
The instantaneous coupling adds new terms to the action
\[
\delta S = \frac{\mu}{2q} [G_1(3\beta/4 + \epsilon, \beta/4 - \epsilon) - G_1(\beta/4 - \epsilon, 3\beta/4 + \epsilon) + G_1(\beta/4 + \epsilon, 3\beta/4 - \epsilon) - G_1(3\beta/4 - \epsilon, \beta/4 + \epsilon)] \tag{5.12}
\]
Therefore the effective action becomes
\[
S = \frac{N}{2} \left( \log \frac{\det(\partial_\tau - \Sigma)}{\det(\partial_\tau - \Sigma_1)} \right)^{\alpha-1} + \int \int \left[ \alpha \Sigma_1 G_1 + (1 - \alpha) \Sigma_2 G_2 - \frac{J^2}{q} (\alpha G_1 + (1 - \alpha) G_2)^q \right] + \delta S \tag{5.13}
\]
which leads to the following equation of motion
\[
G_i = (\partial_\tau - \Sigma_i)^{-1}, \tag{5.14}
\]
\[
\Sigma_1 = J^2 (\alpha G_1 + (1 - \alpha) G_2)^q - \frac{\mu}{q \alpha N} \tilde{\delta}, \tag{5.15}
\]
\[
\Sigma_2 = J^2 (\alpha G_1 + (1 - \alpha) G_2)^q - \tilde{\delta}, \tag{5.16}
\]
\[
\tilde{\delta} = \delta_{\tau, \beta/4 - \epsilon} \delta_{\tau', 3\beta/4 + \epsilon} - \delta_{\tau, 3\beta/4 + \epsilon} \delta_{\tau', \beta/4 - \epsilon} - \delta_{\tau, \beta/4 + \epsilon} \delta_{\tau', 3\beta/4 - \epsilon} + \delta_{\tau, 3\beta/4 - \epsilon} \delta_{\tau', \beta/4 + \epsilon} \tag{5.17}
\]
where \( i = 1,2 \) and \( \delta_{a,b} \) is short for \( \delta(a - b) \). As expected \( \Sigma_2 \) and \( G_2 \) does not directly have a delta function in their equations of motion. However, the two parts interact with each other and the twist boundary condition for \( G_1 \) affect \( G_2 \) accordingly. As discussed in Sec. 2.2, the equations of motion only captures the linearized version of the twist boundary condition. Luckily, in the large \( q \) solution, this is enough. To be precise, let us expand
\[
\left[ G_i \right] \approx \left[ G_0 \right] + \left[ G_0 \right] \left[ \Sigma_i \right] \left[ G_0 \right] \tag{5.18}
\]
Defining \( G_+ = \alpha G_1 + (1 - \alpha) G_2 \) and \( G_- = G_1 - G_2 \), the equations of motion become
\[
\left[ G_+ \right] = \left[ G_0 \right] + \frac{J^2}{q} \left[ G_0 \right] \left[ (2G_+)^q - 1 \right] \left[ G_0 \right] + \frac{\mu}{q \alpha N} \left[ G_0 \right] \left[ \tilde{\delta} \right] \left[ G_0 \right] \tag{5.19}
\]
\[
\left[ G_- \right] = \frac{\mu}{q \alpha N} \left[ G_0 \right] \left[ \tilde{\delta} \right] \left[ G_0 \right] \tag{5.20}
\]
The first equation is exactly the same as the one for \( G_\mu \) in our earlier analysis, and we can solve it with the same ansatz
\[
G_+ = G_0 e^{\sigma^+/(q-1)} \tag{5.21}
\]
where $\sigma_+$ obeys the boundary conditions (3.38)-(3.40). The second equation can be evaluated explicitly

$$G_− = \frac{\mu}{q\alpha N} \sum_\pm [\pm G_0(\tau, \beta/4 \mp \epsilon)G_0(3\beta/4 \pm \epsilon, \tau') \mp G_0(\tau, 3\beta/4 \pm \epsilon)G_0(\beta/4 \mp \epsilon, \tau')].$$

(5.22)

In the fundamental region, the configuration is very simple

$$G_− = -\frac{\mu}{2q\alpha N} \text{ in } c, \quad G_− = 0 \text{ in others} \quad (5.23)$$

Since $G_1 = G_+ + (1 - \alpha)G_−$ and $G_2 = G_+ - \alpha G_−$, they are identical in all subregions of fundamental region except $c$. In subregion $c$, both $G_1$ and $G_2$ have exponential growth after continuation to Lorentz signature as $G_+$ does. However, on the boundary of $c$, the boundary condition for $\sigma_+$ is

$$\sigma_+(\text{inside } c) = \sigma_+(\text{outside } c) - \frac{\mu}{N}$$

(5.24)

To leading order in $1/q$, this shift perfectly cancels the constant shift in $G_-$,

$$G_2(\text{inside } c) \approx \frac{1}{2}(1 + \frac{1}{q}\sigma_+(\text{inside } c)) + \frac{\mu}{2qN}$$

$$= \frac{1}{2}(1 + \frac{1}{q}\sigma_+(\text{outside } c)) \approx G_2(\text{outside } c)$$

(5.25)

which shows that $G_2$ is continuous. This analysis clearly shows the crucial feature of traversable wormhole teleportation that the coupled qubits between two systems can be chosen independently from the teleported qubits.

Note that the number of coupled qubits must be of order $N$ to guarantee that the path integral over the effective action (5.13) is dominated by the classical solution. Otherwise, one must treat all $\alpha N \sim O(1)$ Majorana Fermions with full quantum corrections, which is beyond the regime of validity of the calculations in this paper.

### 5.3 Teleportation of multiple qubits

If we want to teleport $n$ qubits together, we can simply prepare $R = \bigcup_i R_i$, $T = \bigcup_i T_i$ and $Q = \bigcup_i Q_i$ for $i = 1, \cdots, n$ and apply $n$ SWAP operators associated to $n$ different (Dirac) fermions in the SYK model. As these SWAP operators have different fermion indices, they do not talk to each other, due to the $SO(N)$ approximate symmetry. Therefore, correlation functions with twist boundary conditions factorize into independent channels in the large $N$ limit. It follows that the reduced density matrix between $R$ and $T$ is tensor product of $n$ identical matrices, each of which is given as before (2.13). The caveat in this argument is that the number of teleported qubit $n$ must be $o(N)$, otherwise the factorization of the correlation functions at large $N$ breaks down. Since $o(N) < O(N)$, this is consistent with the teleportation information bound: 2 classical bits can only teleport at most one qubit. This is also consistent with the upper bound of total number of teleported qubit from gravitational computation [36].

Although the traversable wormhole teleportation does not teleport the maximal number of qubits, it does have an advantage that the qubits are strongly error protected [37].
Indeed, as we can choose arbitrary $O(N)$ Majorana fermions in the interaction $V$, it does not matter what happens to other uncoupled ones. In the quantum information language, when some qubits are corrupted or erased, we can still measure other intact qubits in the $l$ system to complete the teleportation protocol. Holographically, the dual picture is a qubit traveling through a traversable wormhole. As the location of qubit is in the deep interior, it is not sensitive to local boundary changes, which correspond to simple ($O(1)$ qubit) errors.

### 5.4 Classical simulation and separability

As we have seen in Sec. 4.3, an appropriate choice of SWAP operator leads to almost perfect fidelity in the large $q$ limit. However, in the interference regime and for other choices of the SWAP in the large $q$ solution, the mutual information can still be $O(1)$ although submaximal, so there is not perfect teleportation. Here we examine in more detail whether teleportation in those cases really communicates quantum information that cannot be simulated by a purely classical communication protocol. In other words, we need to investigate if $\rho_{RT}$ is separable.

Generally, a density matrix on two systems $\rho_{RT}$ is separable if it can be written in the form of sum of tensor products of density matrices in each subsystem,

$$
\rho_{RT} = \sum_i p_i \rho_R^i \otimes \rho_T^i, \quad \sum_i p_i = 1, \quad p_i > 0, \quad \forall i
$$

(5.26)

Here $p_i$ can be understood as the classical probability for each tensor product state. By definition, it is clear that the mutual information is purely classical if the density matrix $\rho_{RT}$ is separable. In such a case, we could achieve the same result with classical simulation, and our quantum teleportation protocol would have failed.

For a general bipartite density matrix, determining if it is separable is an NP-hard problem [38, 39]. However, for our pair of single qubit systems, the sufficient and necessary condition is the Peres-Horodecki criterion [40, 41], which states that if the partial transposed density matrix has a negative eigenvalue, then the density matrix is quantum entangled. By (2.64)-(2.66), the partial transpose of the density matrix $\rho^T_R$ is simply obtained by exchanging $\rho_{14}$ with $\rho_{23}$.

In our large $q$ solution, the eigenvalues of $\rho^T_R$ are

$$
\frac{1}{4}(1 + \mathcal{K}^2) \quad \text{(multiplicity 2)}, \quad \frac{1}{4}(1 \pm 2\mathcal{K} - \mathcal{K}^2)
$$

(5.27)

The first expression is always positive and the second one could be negative when $|\mathcal{K}| > \sqrt{2} - 1 \approx 0.414$. For low temperatures with the improved protocol, the maximum value of $|\mathcal{K}|$ is given by (4.37), which satisfies this bound when $0.094q < p < 1.260p$. For high temperatures with the improved protocol, the maximum value of $|\mathcal{K}|$ is given by (4.40), which satisfies the bound when $p > 0.336q$. In those cases, $R$ and $T$ have some quantum entanglement.

In the interference regime, the eigenvalues of $\rho^T_R$ are

$$
\frac{1}{4}(1 + 2U^2 - 2t^2 \cos \mu \langle V \rangle) \quad \text{(multiplicity 2)},
$$

$$
\frac{1}{4}(1 - 2U^2 + 2U^2 \cos \mu \langle V \rangle \pm 2U \sin \mu \langle V \rangle),
$$

(5.28)

(5.29)
where $U \equiv -i \langle \psi_l(-t')\psi_r(t) \rangle \in (0,1/2)$. The first expression is always positive and the second one could be negative when

$$\frac{1}{2} \geq U > -\sin \mu \langle V \rangle + \sqrt{(1 - \cos \mu \langle V \rangle)(3 + 2 \cos \mu \langle V \rangle)} \over 2(1 - \cos \mu \langle V \rangle) \tag{5.30}$$

It is clear that in the high temperature limit, $U = |V| = 1/2$ and above inequality is satisfied when $2.294 + 4k\pi < \mu < 7.131 + 4k\pi$ for $k \in \mathbb{Z}$. In this case, there is teleportation of some quantum information in the interference regime.

6 Conclusion

In this paper, we proposed a simple teleportation protocol using a pair of SYK systems. The protocol requires the two systems prepared in the highly entangled thermofield double state. There are three steps:

1. Apply a SWAP operation in one system to insert a qubit at early (negative) time $t = -t_{in}$;
2. Evolve the state to $t = 0$ and apply a weak coupling between two SYKs;
3. Evolve the state to $t \approx t_{in}$ and apply a SWAP to extract the qubit.

We calculated the mutual information $I_{RT}$ between a reference system and the final qubit to confirm the effectiveness of this protocol. The protocol has a clear holographic interpretation in which the teleported qubit goes through a traversable wormhole in a nearly AdS$_2$ spacetime. At low temperature, the result matches the semiclassical gravity analysis in two aspects: first, we see a high peak in $I_{RT}$ at a specific time that is related to the geodesics through the traversable wormhole; second, there is a range of time in which time ordering of the signal is preserved. We take these as signs that the information travels smoothly through the throat of a traversable wormhole. As the temperature increases, we identify some “stringy” corrections to correlation functions that will soften the peak in $I_{RT}$.

Our protocol is quite similar to standard teleportation in the sense that the weak coupling between two SYKs can be implemented as a measurement in one system and a corresponding unitary in the other. However, the measurement in our protocol is in the computational basis thanks to scrambling, and the teleported qubit is highly error protected. This protocol allows teleportation of $o(N)$ qubits simultaneously, at the cost of communication of $O(N)$ bits of classical information, which obeys the information bound on quantum teleportation.

The protocol can be improved to approach perfect fidelity by an appropriate choice of SWAP operator. For large $q$ SYK at low temperatures, using a SWAP of the qubit into $q/2 + 1$ Majorana fermions, we find that the mutual information $I_{RT}$ tends to 1 when $q \to \infty$. Similarly, at high temperature, SWAP of the qubit into $p$ Majorana fermions with $p \gg q$ also results in mutual information close to 1.
At very late times, we also analyzed the teleportation effect in the fully scrambled interference regime. It turns out that the interference effect makes teleportation possible only at high temperature rather than low temperature with our simple protocol. This corresponds to very late time black holes, for which Kitaev and Yoshida proposed an algorithm [11] involving complicated operators to decode the scrambled qubit. Our protocol has a much simpler structure and works for both around the scrambling time at all temperatures, and for very late times at high temperature.

A Solution of $\sigma$

In this appendix, we provide the details of how to determine $\sigma$. Let us assume that

$$g^\mu_0 = \overline{SL}_\mu(f^{-\mu}_0) = \frac{\tilde{a}_\mu + \tilde{b}_\mu f^{-\mu}_0}{\tilde{c}_\mu + \tilde{d}_\mu f^{-\mu}_0} \quad (A.1)$$

which leads to

$$\langle \overline{SL}_\mu(f^{-\mu}_0), \overline{SL}_{-\mu}(f^{-\mu}_0) \rangle \simeq \langle \overline{SL}_{-\mu}(f^\mu_0), \overline{SL}_{-\mu}(f^{-\mu}_0) \rangle,$$

$$\overline{SL}_{-\mu}(f) = \frac{\tilde{d}_{-\mu} + \tilde{b}_{-\mu} \mathcal{J}^2 f}{\mathcal{J}^2 (\tilde{c}_{-\mu} + \tilde{d}_{-\mu})} \quad (A.2)$$

where the first $\simeq$ is due to the symmetry (3.43) and the second $\simeq$ is due to the global $SL(2)$ symmetry (3.29) of the large $q$ solution. When $\mu = 0$, we see from (3.36) that $\overline{SL}$ is the identity, from which we can fix $\tilde{b}_\mu \tilde{c}_\mu - \tilde{a}_\mu \tilde{d}_\mu = 1$ because we want the solution to smoothly reduce to the $\mu = 0$ case. It follows that

$$\tilde{a}_\mu + \tilde{b}_\mu f^{-\mu}_0 = \frac{\tilde{d}_{-\mu} + \tilde{b}_{-\mu} \mathcal{J}^2 f_0^{-\mu}}{\mathcal{J}^2 (\tilde{c}_{-\mu} + \tilde{d}_{-\mu})},$$

$$\Longrightarrow \tilde{a}_\mu \mathcal{J}^2 - \tilde{d}_{-\mu} = \tilde{b}_\mu - \tilde{b}_{-\mu} = \tilde{c}_\mu - \tilde{c}_{-\mu} = 0 \quad (A.3)$$

Similarly, $f^\mu_0$ must be related to $f^\mu_{0s}$ by an $SL(2)$ transformation, explicitly

$$f^\mu_0 = sl_\mu (f^\mu_{0s}) = \frac{\alpha_\mu + \beta_\mu f^\mu_{0s}}{\gamma_\mu + \delta_\mu f^\mu_{0s}} \quad (A.4)$$

This $SL(2)$ squares to the identity because $f^\mu_0 = sl_\mu (f^\mu_{0s}) = sl_\mu (sl_\mu (f^\mu_{0}))$, which implies that

$$\beta_\mu + \gamma_\mu = 0, \text{ or } \alpha_\mu = 0, \delta_\mu = 0 \quad (A.5)$$
Accordingly, we can follow similarly to the derivation of (A.2) to get
\[ f_\ast = -\frac{1}{\mathcal{F}} \sin 2\nu + \cos 2\nu \cdot f \]
which has nonzero \( \alpha_\mu \) and \( \delta_\mu \) under \( \tau \) reflection. Therefore we must take the former choice in (A.5) and fix \( \beta_\mu^0 + \alpha_\mu \delta_\mu = 1 \).

Since we have two \( SL(2) \) symmetries in region \( b \), they need to be consistent with each other
\[ (f_\mu^0, \tilde{S}_\mu(f_\mu^0)) \simeq (f_\mu^0, \tilde{S}_\mu(f_\mu^{-\mu})) \]
In other words, as \( sl_\mu \) transforms \( f_\mu^0 \) to \( f_\mu^{-\mu} \), it must transform \( \tilde{S}_\mu(f_\mu^0) \) to \( \tilde{S}_\mu(f_\mu^{-\mu}) \) accordingly. We can follow similarly to the derivation of (A.2) to get
\[ sl_\mu^{-1}(\tilde{S}_\mu(f)) = \tilde{S}_\mu(sl_\mu(f)) \]
which leads to
\[ \tilde{a}_\mu \beta_\mu + \tilde{c}_\mu \delta_\mu / \mathcal{J}^2 = \tilde{b}_\mu \alpha_\mu - \tilde{a}_\mu \beta_\mu , \]
\[ \tilde{b}_\mu \beta_\mu + \tilde{d}_\mu \delta_\mu / \mathcal{J}^2 = \tilde{a}_\mu \delta_\mu + \tilde{b}_\mu \beta_\mu , \]
\[ \mathcal{J}^2 \tilde{a}_\mu \alpha_\mu - \tilde{c}_\mu \beta_\mu = \tilde{d}_\mu \alpha_\mu - \tilde{c}_\mu \beta_\mu , \]
\[ \mathcal{J}^2 \tilde{b}_\mu \alpha_\mu - \tilde{d}_\mu \beta_\mu = \tilde{c}_\mu \delta_\mu + \tilde{d}_\mu \beta_\mu , \]
which can be solved as
\[ \tilde{a}_\mu = \frac{-\tilde{b}_\mu \beta_\mu \pm \sqrt{\tilde{b}_\mu^2 - \tilde{d}_\mu \delta_\mu / \mathcal{J}^2}}{\delta_\mu}, \]
\[ \tilde{c}_\mu = \mathcal{J}^2 \tilde{b}_\mu (1 + \beta_\mu \beta_\mu) \mp (\beta_\mu + \beta_\mu) \sqrt{\tilde{b}_\mu^2 - \tilde{d}_\mu \delta_\mu / \mathcal{J}^2}}{\delta_\mu \delta_\mu} \]
with \( \tilde{b}_\mu = b_\mu \), \( \tilde{a}_\mu = \mathcal{J}^2 \tilde{a}_\mu \), and \( \alpha_\mu = (1 - \beta_\mu^2) / \delta_\mu \) by definition. These are all constraints resulting from the symmetries and smoothness requirements.

We can apply a similar analysis to regions \( a \) and \( e \). There is only one symmetry in each of these two regions, so the constraint is much weaker. Taking all these into account, we assign functions to each subregion in Fig. 4 with only three functions \( f_\mu^0 \), \( g_\mu \), and \( h_\mu \) (here we simplify notation \( f_\mu^0 \to f_\mu \)), and four \( SL(2) \) transformations \( \tilde{S}_\mu, \overline{S}_\mu, \overline{S}_\mu \), and \( sl_\mu \) to be determined, where \( \tilde{S}_\mu \) and \( \overline{S}_\mu \) obey
\[ \dot{a}_\mu \mathcal{J}^2 - \dot{\tilde{d}}_\mu = \dot{\tilde{b}}_\mu - \dot{b}_\mu = \dot{\tilde{c}}_\mu - \dot{c}_\mu = \dot{\tilde{a}}_\mu \mathcal{J}^2 - \dot{\tilde{d}}_\mu = \dot{\tilde{b}}_\mu - \dot{b}_\mu = \dot{\tilde{c}}_\mu - \dot{c}_\mu = 0 \]
with \( \dot{b}_\mu \dot{c}_\mu - \dot{a}_\mu \dot{d}_\mu = 1 \) and \( \dot{a}_\mu \dot{c}_\mu - \dot{a}_\mu \dot{d}_\mu = -1 \). Here the normalization for \( \overline{S}_\mu \) is \(-1\) to agree in the \( \mu = 0 \) case with \( g_\mu^0 = \overline{S}_\mu (g_\mu^{-\mu}) = f \) in (3.36).

The twist boundary conditions on the four blue segments in Fig. 4 are given by (3.45)-(3.48). We can use these equations to determine both \( \overline{S}_\mu \) and \( \tilde{S}_\mu \) based on the value of \( f_\mu \) and \( g_\mu^0 \) on the boundaries. For notational simplicity, we define \( f_\pm \equiv f_\mu (\tau_\pm) \),
\( f^\mu_{\pm} \equiv f^\mu(-\tau_{\pm}) \) and similarly for \( g^\mu_1 \) and their derivatives. Using (A.13) and \( f^\mu \) we can determine \( g^\mu_- \) and \( g^\mu_- \) via (3.46). Based on these values, we can determine \( \SL^\mu \) completely via (3.47), the constraints (A.14) and the value (A.13). It turns out that

\[
\hat{b}_\mu = \mp \tilde{c}_\mu, \quad \hat{c}_\mu = \mp \hat{b}_\mu, \quad \hat{a}_\mu = \pm \tilde{a}_{-\mu}, \quad \hat{d}_\mu = J^2 \tilde{a}_{-\mu} \tag{A.15}
\]

As both signs give the same \( \SL^\mu \), we will choose the lower sign without loss of generality.

To solve for \( \SL^\mu \) is similar. The only difference is that it involves \( f^\mu_+ \) that is related to \( f^\mu_- \) via \( s_{\mu} \). It turns out that one can determine \( \bar{a}_\mu, \bar{b}_\mu, \bar{c}_\mu \) and \( \bar{d}_\mu \) explicitly in terms of \( \tilde{b}_\mu, \beta_{\pm\mu}, \delta_{\pm\mu} \) and \( f^\mu_\pm \) only. However, the expression is very complicated and we do not reproduce it here. At this point, the free parameters have been reduced to \( \tilde{b}_\mu, \beta_{\pm\mu}, \delta_{\pm\mu} \).

As argued in Sec. 3.2.3, there are still too many degree of freedom to uniquely fix the solution. Taking the ansatz (3.51), we immediately get

\[
\beta_\mu = \beta = \cos 2v, \quad \delta_\mu = \delta = -J \sin 2v \implies \tilde{a}_\mu = \tilde{d}_\mu = \tilde{a}_\mu = \tilde{d}_\mu = 0, \quad \tilde{c}_\mu = \tilde{b}_\mu = 1 \tag{A.16}
\]

On the other hand, we know

\[
(\SL^\mu(g^-_{1\mu}), g^\mu_1) \simeq \left( \frac{a + bf}{c + df}, f \right), \quad bc - ad = 1 \tag{A.17}
\]

for some \( a, b, c, d \). Applying this to the formula for \( e^\sigma \) and checking the UV condition, we find

\[
b = c = \cos \varphi, \quad d = -aJ^2 = -J \sin \varphi,
\]

\[
e^\sigma = \frac{\omega^2}{J^2 \cos^2(\omega \tau_{ab} + \varphi),} \quad \omega = J \cos(\varphi - \omega \beta/2) \tag{A.18}
\]

Now we can forget about \( \SL^\mu \) and directly impose the symmetry conditions: \( \mu \to -\mu, \quad \tau_{ab} \to -\tau_{ba} \). This requires that \( \varphi \) is invariant under \( \mu \to -\mu \). In order to more simply satisfy the twist boundary condition, we use the global \( SL(2) \) to write

\[
\left( \frac{a + bf}{c + df}, f \right) \simeq \left( F \left( \frac{a + bf}{c + df} \right), G(f) \right) \tag{A.19}
\]

where \( F \) is given by (3.29)

\[
F(f) = \frac{D_\mu - C_\mu J^2 f}{J^2 (-B_\mu + A_\mu J^2 f)} \tag{A.20}
\]

Let us check twist boundary conditions using (3.51), (A.20) and (A.18):

\[
G(f) = f_, \quad G'(f) = e^{-\mu/N}, \tag{A.21}
\]

\[
F \left( \frac{a + bf_-}{c + df_-} \right) = f_-, \quad F' \left( \frac{a + bf_-}{c + df_-} \right) \left( c + df_- \right)^2 = e^{\mu/N} \tag{A.22}
\]

These four equations determine the four variables: \( A_\mu, B_\mu, C_\mu, \varphi \), in which

\[
\cot \frac{\varphi}{2} = \cot 2\omega \tau_- \text{ or } \varphi = 0 \tag{A.23}
\]
As we would like to match on to the $\mu = 0$ solution smoothly, we must choose the second case. It follows that
\begin{align}
A_\mu &= \frac{2f_- \sinh \frac{\mu}{2N}}{1 + J^2 f_- f_{-s}}, \quad B_\mu = \frac{\mathcal{J}^2 f_- f_{-s} e^{\mu/(2N)} + e^{-\mu/(2N)}}{1 + J^2 f_- f_{-s}}, \\
C_\mu &= \frac{\mathcal{J}^2 f_- f_{-s} e^{-\mu/(2N)} + e^{\mu/(2N)}}{1 + J^2 f_- f_{-s}}, \quad D_\mu = \frac{2\mathcal{J}^2 f_- \sinh \frac{\mu}{2N}}{1 + J^2 f_- f_{-s}}
\end{align}
and UV condition becomes
\begin{equation}
\omega = \mathcal{J} \cos(\omega \beta/2)
\end{equation}
Lastly, we will solve for $g^\mu$. This is easier to do in terms of the unshifted $\tau_a$ coordinate. In the unshifted coordinate,
\begin{equation}
f^\mu = \frac{\tan(\omega(\tau - \beta/2) + v)}{\mathcal{J}} = -\frac{1}{2} \tan \frac{\omega \beta/2 + f}{1 + \mathcal{J} \tan \omega \beta/2} 
\end{equation}
This is an $SL(2)$ transformation. We can simply assume that in the unshifted coordinate $f^\mu = f$, and find the most general $g^\mu$ that satisfies the UV condition. Then doing a corresponding $SL(2)$ transformation (3.29) to $g^\mu$ will give the solution in the shifted coordinate. Let us assume $g^\mu = H(f)$ for some functional of $f$. The UV condition becomes
\begin{equation}
\frac{H'(f)f^2}{(1 + J^2 H(f)f)^2} = 1
\end{equation}
Note that for our special choice of $f$, $f'$ is related to $f$ by
\begin{equation}
f^2 = \frac{\omega^2}{\mathcal{J}^2} \sec^4(\omega \tau + v) = \frac{\omega^2}{\mathcal{J}^2} (1 + J^2 f^2)^2
\end{equation}
Plug this back to (A.28) and solve for $H$ as
\begin{equation}
H(f) = \frac{1}{J} \frac{h_\mu \sin(\omega \tau + v - \phi) - e^{2(\omega \tau + v)} \tan \phi \sin(\omega \tau + v + \phi)}{h_\mu \cos(\omega \tau + v - \phi) - e^{2(\omega \tau + v)} \tan \phi \cos(\omega \tau + v + \phi)}
\end{equation}
where $\omega = \mathcal{J} \cos \phi$ and $h_\mu$ is an integration constant. Comparing with (A.26), we have $\phi = \omega \beta/2$. Before shifting it back to the new coordinate $\tau_a \rightarrow \tau_a + \beta/2$, we apply (A.27) to $f$ and an associated $SL(2)$ transformation to $g^\mu$:
\begin{equation}
g^\mu \rightarrow -\frac{1}{2} \tan \frac{\omega \beta/2 - g^\mu}{1 + \mathcal{J} \tan \omega \beta/2 \cdot g^\mu}
\end{equation}
which leads to
\begin{equation}
g^\mu = \frac{1}{\mathcal{J} e^{2(\omega \tau + v)} \tan \omega \beta/2} \frac{\sin(\omega \tau + v) - h_\mu \sin(\omega \tau + v - \omega \beta)}{\cos(\omega \tau + v + \omega \beta) - h_\mu \cos(\omega \tau + v - \omega \beta)}
\end{equation}
Solving twist boundary condition, we find
\begin{equation}
h_\mu = \frac{e^{2(\omega \tau + v)} \tan \omega \beta/2 (e^{-\mu/N} - 1) \sin(\omega \tau + v) - \cos \omega \beta/2 \cos(\omega \tau - v)}{\cos \omega \beta/2 \cos(\omega \tau + v) - \cos 2(\omega \tau - v) \cos(\omega \tau - \omega \beta + v) + e^{-\mu/N} \sin(\omega \tau + v) - \omega \beta/2 \cos(\omega \tau - v) - \omega \beta/2 \cos(\omega \tau + v) - \omega \beta/2 \cos(\omega \tau - v) - \omega \beta/2 \cos(\omega \tau + v) - \omega \beta/2 \cos(\omega \tau + v) - \omega \beta/2 \cos(\omega \tau - v)}
\end{equation}
which vanishes when $\tau_+ \rightarrow \tau_-$. This is a consistency requirement. It is important that we need a nontrivial $h_\mu$ for a consistent solution to our problem, even though in the end we do not need it as we will take the $\tau_+ \rightarrow \tau_-$ limit.
