Introduction: Studies of aggressive behaviors in a nonforensic mental health setting have focused primarily on the inpatient ward and, on event prediction, using behavior-based clinical rating scales. Few studies have specifically targeted aggressive behaviors in the psychiatric emergency service or determined whether assessing the demographic and clinical characteristics of such patients might prove useful for their more rapid identification.

Methods: We used a prospectively acquired database of over 20,900 visits to four services in the province of Quebec, Canada, over a two-year period from September 2002 onwards. A maximum of 72 variables could be acquired per visit. Visits with aggression (any verbally or physically intimidating behavior), both present and past, were tagged. Binary logistic regressions and cross-tabulations were used to determine whether the profile of a variable differed in visits with aggression from those without aggression.

Results: About 7% of visits were marked by current aggression (verbal 49%, physical 12%, verbal and physical 39%). Including visits with a “past only” history of aggression increased this number to 20%. Variables associated with aggression were gender (male), marital status (single/separated), education (high school or less), employment (none), judicial history (any type), substance abuse (prior or active), medication compliance (poor), type of arrival to psychiatric emergency services (involuntary, police, judiciary, landlord), reason for referral (behavioral dyscontrol), diagnosis (less frequent in anxiety disorders), and outcome (more frequently placed under observation or admitted).

Conclusion: Our results suggest that many state-independent variables are associated with aggressive behaviors in the psychiatric emergency service. Although their sum may not add up to a specific patient profile, they can nevertheless be useful in service planning, being easily integrated alongside state-dependent rating scales in a triage and/or observation instrument for daily use in the psychiatric emergency service.

Keywords: psychiatric emergency service, aggressive behaviors, epidemiology

Introduction

Disruptive acts of violence in a nonforensic mental health setting can take an emotional toll on both staff and patients. Although widespread and observable in almost all clinical settings,1-5 aggressive behaviors have been most frequently studied in inpatients.1,6-9 Generally, assaultive patients have been described as being either older schizophrenic males or younger, gender nonspecific patients with personality disorders.1,10 Both types of profiles are often associated with a history of comorbid substance abuse, as well as a history of violence towards others.1,4,7,8

The psychiatric emergency service (PES) is a major hub in the mental health care delivery system. In its most elementary form, it consists of the interaction between a
psychiatrist (or health care professional) and a patient within the framework of a crisis situation. Studies specifically targeting aggressive behaviors in the PES have been fewer in number, as well as less consistent in providing definitive clinical profiles. Estimates of their frequency in the PES have ranged from 6% to 17% of all visits. Although an acute psychotic state (regardless of its origin) and recent aggressive behaviors prior to a PES visit appear to be associated, variables such as age, gender, or substance abuse have shown less consistency. This inconsistency may not only be due to the relatively small number of available PES studies on this topic, but also to the generally broader PES diagnostic profile (compared with the inpatient setting) and to a host of variables (some sociodemographic, some even environmental) that do not have inpatient counterparts. Matching aggressive behaviors in the PES to a consistent patient profile was the primary objective of our study. Such a finding may prove useful at the triage level, especially if combined with more “state or emotional-based” rating instruments typically used to assess such high-risk behaviors. We pursued this objective by using a prospectively acquired database of over 20,900 PES visits made to four PES in the province of Quebec, Canada, over a two-year period.

Methods

Data collection was as previously described. Clinical and demographic data were obtained from patients 18 years of age and older visiting four major PES between September 1, 2002 and August 31, 2004. Two of these services were in the city of Montreal in Quebec, Canada. The first was in a downtown university teaching hospital and the second was within a university affiliated psychiatric institute near the downtown core. This latter PES did not have a medical emergency department or prior medical triage, and largely functioned as a “walk-in clinic”. Each PES in metropolitan Montreal is assigned a geographic catchment area, and citizens within it are obliged to seek acute psychiatric care at that service only. Approximately 4.8% of all patients who underwent triage in the emergency department of the general hospital PES were referred for a psychiatric assessment. Two sites were in cities other than Montreal. One was in Quebec City (300 km east of Montreal, with approximately 500,000 citizens) and the other in Saint-Jean-sur-Richelieu (40 km south of Montreal, with approximately 90,000 citizens). This latter site differed from the others by not having an observation area with short-term beds.

A maximum of 72 variables could be acquired per visit. The main table contained administrative variables (eg, chart number, name, and gender). Linked tables contained variables pertinent to the consultation process, eg, date and time of arrival, reasons for the referral, psychosocial stressors prior to the visit, referral source, ethnicity, employment, residential status, disposition, and DSM-IV (Diagnostic and Statistical Manual of Mental Disorders, 4th Edition) diagnoses (three per visit). Qualitative data were also acquired, including a subjective rating by the nursing staff of the level of aggression upon arrival to the PES (verbal aggression, physical aggression, both, none at all). Staff responses, eg, verbal pacification, isolation without restraints, or isolation plus restraints, were also categorized. All variables in the database were listed in a paper format, which was used as the primary triage instrument for patients visiting the four services during the two-year period. The completed forms were forwarded to the principal investigator on a weekly basis for data entry.

Many strategies were used in order to minimize diagnostic uncertainty. First, because over 60% of PES visits have been shown to occur within the daytime hours, only services that were covered on weekdays by experienced, regular daytime psychiatric staff with over five years’ experience in the PES setting were included. None of the four sites provided midnight to 7 am assessments. Patients referred from the emergency department during this time period were kept in the psychiatric observation area for assessment in the morning. As such, during weekdays, well over 70%–80% of patients were assessed by the regular PES staff. Most staff obtained their medical and specialty training at one the four medical faculties in the province, and thus shared a common set of methodological, ethical, and cultural standards. Second, diagnoses made using DSM-IV guidelines during nonstructured clinical interviews were obtained either directly from staff after patient assessment or from the patient’s chart. Third, diagnoses were grouped into broad categories, which included “none”, “adjustment”, “anxiety”, “personality”, “affective”, “schizophrenia”, “psychosis not otherwise specified”, “substance abuse”, and “organic mental disorders”. Fourth, for patients with two or more visits, a “most probable” primary diagnosis was attributed, which was the diagnosis most frequently given. The second most frequently attributed diagnosis was retained as comorbidity. Fifth, as previously reported, from 65%–80% of frequent users at all sites were at one point in time under multidisciplinary outpatient care and, as such, any diagnostic uncertainty could be clarified with the treating team.
Statistical analysis

Data was analyzed using Systat Version 13. The dataset for this study comprised 13,592 patients making 20,963 visits. Most variables were of the nominal type (binary or with multiple categories). Preliminary analyses consisted of constructing contingency tables where the binary dependent variable (presence or absence of violence) was tabulated with an independent predictor variable (e.g., gender). If the $P$ values for the Pearson Chi-square and the likelihood ratio Chi-square were $<0.05$, the data were retabulated using a goodness of fit model to determine if the profile of the dependent variable differed significantly from the independent predictor variable using the distribution ratios of visits marked by aggression as the expected frequencies. Only data for which the two procedures were significant are presented in the Results section. In addition, binary logistic regressions and their resulting odds ratios (OR, with 95% confidence intervals [CI]) were used to determine the strength and direction of an association between the dependent and independent predictor variable.

This study was approved by the scientific subcommittees of the institutional review boards at all sites other than at the psychiatric institute, and was exempted from full review. Full institutional review board approval was required and obtained at the psychiatric institute site.

Results

Overall, 19.7% of all visits (4134 of 20,963 in total made during the observation period) were tagged as having either a present or a past history of aggressive behaviors in the PES. In 4% of visits (167 of 4134) marked by aggressive behaviors, a “current or past” specification was not tagged, and these were dropped from any further statistical analyses. Of the remaining 3967 visits, 22.4% ($n = 888$) were tagged as de novo “current” cases, 16.5% ($n = 654$) as “current” but also having a “past” history of aggressive behaviors in the PES, and in 61% ($n = 2425$) of cases there was a “past” history of aggressive behaviors in the PES only. Unless stated otherwise, most statistical procedures, with the exception of those pertaining to gender and age, were performed on patients presenting with current aggressive behaviors ($n = 1542$) who constituted 7.4% of all PES visits.

In visits from patients with a current history of aggressive behaviors, the nature of the aggression was documented in 1129 cases, and was verbal in 49%, physical in 12%, and both verbal and physical in 39%. The staff response to aggressive behaviors was documented in 1062 incidents, and comprised isolation/seclusion (23%), physical restraints (7%), both (21%), and in 50% of cases staff responded by using a verbal pacification approach.

Sociodemographic variables

Gender differences were clearly in evidence. The male/female percentage distribution of patients without aggressive behaviors was 49/51 ($n = 16,829$), whereas that of visits from patients with a current and/or past history of aggressive behaviors was 60/40 ($n = 3967$). A male/female percentage difference was evident in all groups of visits from patients with aggressive behaviors (current 56/44, current and past 62/38, past only 61/39). Overall, males were 1.57 times more likely to have a current and/or past history of aggressive behaviors than women ($P < 0.001, CI 1.46–1.68$).

Age as a predictor variable was then examined (Figure 1). There was a significant, albeit very slight, decrease in the probability ($P < 0.001, OR 0.938, CI 0.927–0.950$) of aggressive behaviors (combined group) with increasing age. This was so whether age was in 5-year or 10-year intervals (from age 20 years onwards) or by using a binary variable, i.e., dividing patients into two age groups, one 20–40 years and the other ≥41 years. The OR was still significant with gender inserted as a binary interactive variable, although it was slightly less robust ($P < 0.001, OR 0.941, CI 0.929–0.953$).

Marital, educational, employment, and residential status were examined next. A current history of aggressive behaviors ($n = 1451$) was more likely to be seen in visits from patients who were single ($P < 0.001, OR 1.43, CI 1.29–1.60$) or divorced/separated ($P < 0.001, OR 1.39, CI 1.20–1.61$). Patients with a high school (or lower) educational status were 1.7 times more likely to present to the PES with aggressive
behaviors than those with a college or university background ($P < 0.001$, CI 1.48–2.00). Those who were unemployed were 1.74 times more likely to present with aggressive behaviors compared with those in either full-time or part-time employment ($P < 0.001$, CI 1.55–1.95).

A history (past or current) of substance abuse was more frequently found in visits from patients with a current history of aggression ($P < 0.001$, two-way tables with either of the two aggression groups as the dependent variable). However, overall, the logistic regression for this model was not significant. A history of any type of prior illegal activity leading to an arrest was assessed in 10,420 visits (928 with aggression and 9492 without aggression) and, as expected, was much more likely in patients with than without aggression ($P < 0.001$, OR 3.15, CI 2.74–3.62).

Arrival to PES

Time of arrival to the PES, as assessed by the number of visits/four-hour periods beginning at midnight, did not differentiate visits marked by aggression from those without aggression, although there was a tendency for those with aggression to congregate between noon to 8 pm. Frequency of use was examined by dividing patients into groups making different visits/four-hour periods beginning at midnight, did not differ from those without (Pearson Chi-square $P < 0.001$, confidence interval [CI] 0.44–0.78, n = 193), with a family member (OR 0.98, CI 0.87–1.19, n = 276), transfer (from another psychiatric emergency service, OR 1.16, P = 0.43, CI 0.81–1.27, n = 59), with a nonpsychiatric caregiver (OR 1.36, P = 0.21, CI 0.84–2.20, n = 24), with a psychiatric caregiver (OR 1.32, P = 0.18, CI 0.89–2.00, n = 40), ambulance (OR 1.6, P < 0.01, CI 1.22–2.10, n = 371), landlord (OR 2.8, P < 0.001, CI 1.78–4.40, n = 32), judiciary (court referrals, OR 4.0, P < 0.001, CI 2.2.7–5.5, n = 15), police (OR 5.0, P < 0.001, CI 3.8–6.6, n = 406), other (all sources other than those listed, OR 2.6, P < 0.001, CI 1.8–3.7, n = 59).

Abbreviations: Nonpsychiatric caregiver; Psychiatric caregiver; Family member; family member.

Visit characteristics

Over 30 reasons for a psychiatric referral were collapsed into nine logical groupings for analysis. The profile for visits with a current history of aggressive behaviors differed markedly from that of those without (Figure 3), primarily due to an increase in the number of referrals for behavioral dyscontrol and a decreased number for depression and anxiety-related disorders. Psychosocial stressors prior to the

Figure 2 Odds ratios (OR) for the various types of arrivals to the psychiatric emergency services for visits with a current history of aggression (n = 1476) versus those without (n = 16,003). Alone (OR 0.58, $P < 0.001$, confidence interval [CI] 0.44–0.78, n = 193), with a family member (OR 0.98, CI 0.87–1.0, n = 276), transfer (from another psychiatric emergency service, OR 1.16, P = 0.43, CI 0.81–1.27, n = 59), with a nonpsychiatric caregiver (OR 1.36, P = 0.21, CI 0.84–2.20, n = 24), with a psychiatric caregiver (OR 1.32, P = 0.18, CI 0.89–2.00, n = 40), ambulance (OR 1.6, P < 0.01, CI 1.22–2.10, n = 371), landlord (OR 2.8, P < 0.001, CI 1.78–4.40, n = 32), judiciary (court referrals, OR 4.0, P < 0.001, CI 2.2.7–5.5, n = 15), police (OR 5.0, P < 0.001, CI 3.8–6.6, n = 406), other (all sources other than those listed, OR 2.6, P < 0.001, CI 1.8–3.7, n = 59).
PES visit were reported in 76% (1127 of 1475 visits) of those marked by aggression and 72% (11,601 of 16,200 visits) of those without. The profiles of the psychosocial stressors differed significantly between visits with and visits without aggressive behaviors ($P < 0.001$, Pearson chi-square). Relational (63% versus 48%), legal (2% versus 1%), and housing-related (7% versus 6%) stressors were more frequent in visits with aggression, whereas the reverse was true for many of the remaining stressors, such as grief/loss (3% versus 6%), illness in self or significant other (6% versus 11%), employment-related (4% versus 9%), financial (3% versus 5%), or other (12% each). Current psychotropic medication was not found to differ in visits from patients with a current history of aggression ($n = 1408$) from those without ($n = 17,303$). However, compliance differed markedly, because visits from patients noncompliant with their medication were twice as likely to be marked by aggression ($P < 0.001$, OR 2.15, CI 1.81–2.55).

The outcome of the consultation process is shown in Figure 6. Noteworthy is the predominance of either observation or hospitalization in visits marked by aggression, compared with those without. Also, patients with visits marked by aggression ($n = 1261$) were three times more likely than those without ($n = 13,674$) to be placed under civil commitment in the PES following the psychiatric assessment ($P < 0.001$, CI 2.66–3.59).

Finally, as previously reported, staff were asked to grade 16,821 visits (14,821 without and 1401 with aggression) qualitatively for both pertinence and urgency. About 71% of visits with aggression and 61% of visits without were judged pertinent and urgent, whereas 26% of visits with aggression and 17% of those without were judged pertinent but not urgent.

The diagnostic profiles of visits with and without aggression are shown in Figure 4. Personality, organic mental, substance abuse disorders and, to a slightly lesser extent, schizophrenia, were the diagnoses primarily observed in visits with aggression. Figure 5 shows the percentage of visits with aggression within each broad diagnostic category. In 44% (609 of 1389) of visits with a present history of aggression and 38% (5554 of 14,463) of those without, a comorbid diagnosis was attributed. Substance abuse and personality disorders were the most frequent comorbid diagnoses (approximately 30% each), irrespective of the presence of aggression.
Approximately 10% of visits in each group were judged neither pertinent nor urgent. An assessment could not be made in 2% of visits in both groups. These profiles differed significantly (Pearson Chi-square $P < 0.001$).

**Discussion**

Overall, aggressive behaviors in this study were found in 7.4% of all visits, a number in line with the few existing publications on this topic. However, noteworthy is that this percentage is most likely to be an underestimation because these behaviors were primarily assessed upon arrival to the PES, which is a major limitation of our data. The most coercive type of staff response, ie, physical restraint, was used in 28% of cases when aggression was current, which is a percentage comparable with the 24% reported by Mignon et al., within the first two hours of admission to the PES of agitated or violent patients. Approximately 50% of aggressive behaviors were dealt with by staff using verbal pacification. Verbal intervention was reported to be the most frequent alternative to physical restraints used in aggressive patients in a census of specialized and non-specialized emergency department and psychiatric emergency departments in the US.

In the present study, we found aggressive behaviors to be prevalent in all broad diagnostic categories, with the possible exception of anxiety disorders. However, anxiety disorders contributed little to the overall PES diagnostic profile (Figure 4) and had the least proportion of visits (“within group”) marked by aggression of all diagnostic categories (Figure 5). Organic mental disorders similarly contributed little to the overall PES diagnostic profile, but had an almost 20% proportion of “within group” visits marked by aggression. Active psychosis (eg, hallucinations, delusional thoughts) as a reason for a psychiatric referral was equally prevalent in visits with and without aggression. Overall, visits tagged with aggression were only marginally more comorbid than those without, and the two diagnostic categories most often reported as comorbidity, substance abuse, and personality disorders, were equally reported in visits without aggressive behaviors.

These results would seem to contrast with the often-reported link between psychoses and aggressive behaviors in the inpatient setting and the results of Oster et al, who reported a moderate correlation with psychosis in the PES. However, the differences here may be more apparent than real. In the present study, we used broad diagnostic categories, rather than state-dependent symptoms. It is possible that creating a psychosis binary variable set (combining schizophrenia, psychosis not otherwise specified, and psychotic variants of the major affective disorders) would have better illustrated such a state effect. Furthermore, the PES, as a front-line system in mental health care delivery, is called upon to assess and, increasingly, to treat a very broad range of psychopathology. This broad range in itself would tend to dilute the importance of any one diagnostic category. Third, diagnostic stability may be a possible limiting factor in this study. Baca-Garcia et al, using a retrospective, semi-administrative database, found that diagnostic stability varied with diagnosis (best for schizophrenia, least for personality disorders) and setting (best in the inpatient, least in the outpatient, intermediate in the PES setting). Using purely administrative databases, the PES has fared worse. Although we used a prospective, non-administrative database combined with a rigorous methodological approach in order to reduce diagnostic uncertainty, such a phenomenon may remain a possible confounding factor in our study.

Age was found to be a marginal explanatory variable, in contrast with previous reports. One possible explanation might be that most PES visits are made by those aged 44 years and younger, making it difficult to separate young aggressive patients from an overall young population. Many sociodemographic variables were indeed significantly more likely to be associated with visits marked by aggression. However, on the whole, many of these variables were somewhat predictable. Visits from single, poorly educated, or unemployed patients and those with a past history of illegal activities, were typically associated with aggressive.
behaviors. A gender difference favoring males was observed overall, and was also observed within each broad diagnostic category (data not shown). That being said, a gender difference in almost all types of violent behaviors is well documented by many national statistical agencies.35,36

Arrival in the evening or night has been associated with a greater risk of aggressive behavior in the medical emergency department and, in at least one report, the PES.37–39 We could not confirm this finding in the present study, although we did find a tendency for visits with aggression to be within the noon to 8 pm time slot. Other PES-specific variables such as frequency of use, were not associated with a higher risk of aggressive behaviors while others were, eg, the type of arrival. Involuntary arrivals, regardless of referral source, markedly increased the risk of aggression. In this same line, patients brought to the PES by the police, judiciary, or their landlords (apartment, group home, residence) showed significantly more aggressive behaviors than those who came alone. Behavioral dyscontrol and suicidal ideation (or acts) accounted for nearly 60% of all reasons for a referral in visits with aggression. Given the importance of substance abuse in visits with aggression (prior history of, as a primary or as a comorbid diagnosis), there were, paradoxically, few referrals specifically for this reason. Rather, referring emergency department physicians appeared to focus on factors such as poor impulse control and suicidal ideation, which are observed in almost 50% of patients with alcohol dependence.40 However, interestingly, the psychiatric nursing staff in these services subjectively graded alcohol or drug abuse as being an important direct and/or indirect contributing factor to many of these visits.

Overall, the sociodemographic and clinical picture is one that evokes a downward-drift type of patient, more typically a younger male, unemployed, single or separated, with a history of substance abuse. Such a patient is more likely to be brought in involuntarily and/or by the police, the judiciary or by a landlord, and to report a stress prior to the visit that is interpersonal in nature. If taking medication, the patient is likely to be noncompliant, and most often referred for behavioral dyscontrol, regardless of the presence or absence of an underlying active or chronic psychosis (although an underlying psychosis is often present in such patients).

The cost of aggressive behaviors in the PES does not appear to be only psychological in nature. For instance, the outcome varied significantly with the presence of aggression. Visits marked by aggressive behaviors were more likely to result in either observation in the PES or hospitalization. Indeed, almost all discharge variables were proportionally lower in visits marked by aggression. Furthermore, the latter also more frequently resulted in civil commitment in the PES, which is an additional financial burden.

**Conclusion**

Care must be taken when generalizing from what are largely regional data, because they may not always accurately reflect national trends. Nevertheless, our results do suggest that many clinical and demographic state-independent variables are associated with aggressive behaviors in the PES. Although their sum may not add up to a specific patient profile, they can nevertheless be useful in service planning, being easily integrated alongside state-dependent rating scales in a triage and/or observation instrument for daily use by the PES.
