Abstract

We propose a general formulation of simplicial lattice gauge theory inspired by the finite element method. Numerical tests of convergence towards continuum results are performed for several SU(2) gauge fields. Additionally, we perform simplicial Monte Carlo quantum gauge field simulations involving measurements of the action as well as differently sized Wilson loops as functions of $\beta$.

Keywords: Lattice gauge theory, QCD, Finite element method

1. Introduction

General introduction. Gauge quantum field theory (QFT) has been extremely successful in modeling the behaviour of fundamental high energy particle physics. This is done using the standard model of particle physics, which is based on the gauge symmetry group $G = U(1) \oplus SU(2) \oplus SU(3)$. Quantum gauge field theories based on such noncommutative gauge groups are also called Yang-Mills theories \cite{1, 2, 3, 4}. Despite the massive successes of this model, there are still large difficulties in calculating low energy properties of quarks and gluons. When restricting to these quantum fields, the standard model reduces to the theory of Quantum Chromodynamics (QCD), with gauge group $SU(3)$. The problems is that through the effect of renormalization, the QCD coupling constant increases as interaction energies is decrease, in such a way that perturbation theory breaks down. This phenomenon is the source of confinement in QCD. Direct paper-and-pen calculation of masses and interactions among low energy bound states of quarks is therefore quite problematic.

Lattice gauge theory. By discretizing QCD onto a lattice, a lot of these difficulties are removed. Lattice gauge theory (LGT) \cite{5, 6} has proven itself to be
a powerful method of doing nonperturbative gauge theory calculations. It has therefore been, still is, and will for a long time be immensely useful in testing QCD against experimental results at low energy.

Usually LGT models are formulated using a hypercubic lattice on a euclidean spacetime. Such a mesh preserves some discrete subgroups of the translational, mirror and 4d rotational symmetries. Note that a clever way of retaining continuous symmetries while working on a lattice is to use random lattices [7, 8, 9].

The models are almost always defined so as to also preserve a discrete gauge symmetry. This has the beneficial effect of enforcing a vanishing gluon mass in the discrete model.

Simplicial lattices. Simplicial meshes have been used for QCD simulations before [10, 11, 12, 13, 14, 15, 16], with promising numerical results. Here, we construct a simplicial gauge theory (SGT) based on the general mathematical concept of a simplicial complex, while preserving gauge invariance. This allows us to define SGT on a very general class of meshes, without restricting ourselves to a particular type of simplicial lattice.

The construction of the gauge invariant SGT action functional is inspired by the finite element method (FEM) most commonly used for solving partial differential equations, particularly on complicated domains [17, 18, 19, 20, 21]. The formalism therefore includes the use of finite element function spaces on simplicial meshes, and the concept of mass matrices. The latter has nothing to do with physical particle masses, and is therefore not to be confused with the usual mass matrix of quantum states within QFT.

Through the use of the FEM formulation, and the massive resources of methods available within that subject area, we hope to gain advantages for QCD simulations in future implementations, in particular with regards to the possibilities of grid refinement. This could be useful in modeling some QCD phenomena, e.g. for highly concentrated gluon flux tubes between quarks where an increase lattice resolution might be desired.

Computer simulation. The mathematical proof of consistency between the SGT and continuous Yang-Mills gauge theory action is described in a companion paper [22], along with a description of the more comprehensive Yang-Mills-Higgs model. In the current article we are content to provide numerical evidence for convergence towards exact continuum results for several choices of gauge field configurations. In addition, we perform Monte Carlo quantum pure gauge field theory simulations for the gauge group $SU(2)$ in temporal gauge, as a proof-of-concept for SGT. Observable measurements include expectation values of the action density as well as a series of different Wilson loops.

Outline. Section 2 contains a short repetition of the fundamental definitions of gauge symmetry and the continuous spacetime Yang-Mills action in subsection 2.1, the basics of traditional lattice gauge theory in subsection 2.2, as well as an introduction to the proposed SGT action in subsection 2.3. In section 3.1 we report on the numerical convergence of the SGT action towards the exact
continuum value for several different cases of SU(2) gauge fields, as well as similar results from traditional LGT. Theoretical results proving convergence for general gauge fields can be found in \[22\]. In section 3.2, we perform Monte Carlo quantum field theory simulations in order to observe that SGT correctly reproduces the basic aspects of the SU(2) quantum field theory. We draw our conclusions in section 4. Appendix A contains a short introduction to elementary aspects of simplicial complexes, and some notes about basis functions and mass matrices that are use in our construction of SGT. Appendix B contains a calculation of strong and weak coupling limits for a Wilson triangle and the action density. Lastly, Appendix C contains a short discussion of some aspects of the numerical computer implementation.

2. Construction

2.1. Continuous gauge theory

Consider the spacetime domain \( \mathbb{M} = \mathbb{R} \times S \), where \( \mathbb{R} \) is time and \( S \subset \mathbb{R}^3 \). The domain \( \mathbb{M} \) represents either lorentzian or euclidean spacetime, in each case equipped with the appropriate metric. In the standard orthonormal \( \mathbb{M} \)-basis \( \{ e_\mu \}_{\mu=0,1,2,3} \), a general point \( x \in \mathbb{M} \) has components \( \{ x^\mu \}_{\mu=0,1,2,3} \). Greek indices run from 0 to 3, and Latin indices from 1 to 3.

Furthermore, in this article we shall consider pure SU(2) gauge theory. However, the construction presented is applicable to any gauge theory based on a compact Lie group \( G \) which can be represented by a subgroup of the complex unitary \( n \times n \) matrices. We define the real-valued scalar product on \( G \) as

\[
g' \cdot g := \Re \text{tr}(g'g^H),
\]

where \( g^H \) is the hermitian conjugate of a matrix \( g \).

The connection between the continuous theory and the discrete simplicial theory is most easily seen in a coordinate free formulation. Thus, we start with a coordinate free formulation, before we give the more familiar coordinate based one.

The free variable in pure Yang-Mills theory with gauge Lie group \( G \) is a gauge potential or more formally a one form \( A \) on \( \mathbb{M} \), with values in the corresponding gauge Lie algebra \( g \). For simplicity of notation, we hereby specify \( G = SU(2) \) and \( g = su(2) \). We split \( A \) into temporal and spatial components \( A = (A_0, A) \). In this context, \( A_0 \) can be thought of as a scalar function\(^1\), and \( A \) as a spatial vector. The curvature (field strength) of such a one form is given by

\[
F(A) = dA + \frac{i}{2}[A, A] = d_0A_0 + dA_0 + dA + i[A_0, A] + \frac{i}{2}[A, A],
\]

where \( d = (d_0, d) \), \( d_0 \) and \( d \) denote exterior derivative in the temporal and spatial directions respectively, and \([\cdot, \cdot]\) is the commutator between Lie algebra elements.

\(^1\)However, not a scalar in the sense of spacetime symmetry transformation properties.
valued one forms. We choose the basis \( \{ t^a \}_{a=1,2,3} \), where \( t^a := \sigma^a/2 \), for \( \mathfrak{su}(2) \), where \( \{ \sigma^a \}_{a=1,2,3} \) are the Pauli matrices. Thus, we can expand the gauge field into components, \( A = A^a t^a \). We also have

\[
[A, A] = \sum_{ab} A^a \wedge A^b [t^a, t^b] = \sum_{abc} i \varepsilon^{abc} A^a \wedge A^b t^c,
\]

where \( \varepsilon^{abc} \) is the antisymmetric Levi-Civita symbol with \( \varepsilon^{123} = 1 \) and \( \wedge \) is the wedge product (exterior product). For later convenience we split the curvature in a temporal and spatial part

\[
F^t(A) = d_0 A + dA_0 + i [A, A_0], \quad F^s(A) = dA + i 2 [A, A].
\]

The action that defines the gauge theory is the functional

\[
S[A] = \frac{1}{4 e^2} \int_M |F(A)|^2 = \frac{1}{4 e^2} \int_M |F^t(A)|^2 + |F^s(A)|^2,
\]

where the norms are generated the metric and \( e \) is the dimensionless Yang-Mills coupling constant.

A gauge transformation is defined by a choice of \( G(x) \in SU(2) \) for each \( x \in M \), and transforms the gauge field as

\[
A_0 \mapsto G (A_0 + d_0) G^{-1}, \quad A \mapsto G (A + d) G^{-1}.
\]

Note that the action \( S[A] \) is invariant under such gauge transformations. For a more precise mathematical exposition, see [22].

A formulation more familiar within physics is obtained by expressing the one form and curvature in coordinates. In other words, one decomposes the one-form \( A^a \) in the basis \( \{ dx^\mu \} \), i.e. \( A^a = \sum_\mu A^a_\mu dx^\mu \). The exterior derivative of such a one-form is given by

\[
dA^a = \sum_{\mu \nu} \partial_\nu A^a_\mu dx^\nu \wedge dx^\mu = \sum_{\mu \nu} \frac{1}{2} (\partial_\nu A^a_\mu - \partial_\mu A^a_\nu) dx^\mu \wedge dx^\nu.
\]

Furthermore, the curvature is given by \( F^a = \sum_{\mu \nu} \frac{1}{2} F^a_{\mu \nu} dx^\mu \wedge dx^\nu \), where

\[
F^a_{\mu \nu} = \partial_\mu A^a_\nu - \partial_\nu A^a_\mu - \varepsilon^{abc} A^b_\mu A^c_\nu.
\]

Finally, the action can be expressed as

\[
S = \frac{1}{4 e^2} \int_M \sum_{\mu \nu a} F^a_{\mu \nu} F^{a \mu \nu} dx,
\]

the usual coordinate dependent expression for the Yang-Mills action functional.
2.2. Lattice gauge theory

To see the connection between lattice gauge theory (LGT) and the simpli-
cial gauge theory (SGT), we will in this section give a brief overview of the
discretization procedure from LGT. For a more complete description see e.g.
[6].

The discretization procedure of both LGT and SGT is based on the following
identity. Consider a small surface Σ with area proportional to $h^2$, where $h$
is a small positive quantity. Then the following identity holds

$$\oint_\Sigma F(A) = \mathcal{H}(A) - 1 + O(h^3),$$

where $\mathcal{H}(A)$ is the holonomy of the one-form $A$, i.e. the parallel transport
induced by $A$ around the boundary of $\Sigma$. This parallel transport is defined as
follows. Given a curve $\gamma : [0,1] \to \mathbb{M}$, such that $\gamma(0) = x$ and $\gamma(1) = y$, the
parallel transport operator along $\gamma$ is given by

$$U_\gamma(x,y) = \text{Pexp}(i \int_\gamma A),$$

where $\text{P}$ denotes path-ordering, and the subscript $\gamma$ is attached to $U$ to denote
the path dependence. In LGT, this quantity is known as the Wilson line.

In LGT, spacetime $\mathbb{M}$ is usually discretized by a uniform hypercubic lattice
$L$. Neighbouring node positions are related through translation vectors
$\{a_\mu\}$ for which we assume $|a_\mu| = h$ for all $\mu$. To each edge $e$ which connects neighbouring
nodes, $n$ and $n + a_\mu$ for some $\mu$, we attach an approximation of the parallel
transport operator along $e$. Thus,

$$U_\mu(n) := \exp(ihA_\mu(n + \frac{1}{2}a_\mu)) \approx U_e(n,n + a_\mu) = \text{Pexp}(i \int_n^{n+a_\mu} A). \quad (10)$$

In LGT this quantity is called a link variable, link matrix or link group element.
Furthermore, given a face $f$ of a cube in the mesh, called a plaquette, we
approximate the holonomy associated to this face as the path-ordered product
of the link variables along its boundary. In other words, if $f$ lies in the $\mu\nu$ plane,
with nodes $n$, $n + a_\mu$, $n + a_\nu$, and $n + a_\mu + a_\nu$, we attach an approximation of the parallel
transport operator along $e$. Thus,

$$U_f(n) := U_{\mu\nu}(n) := U_\mu(n)U_\nu(n + a_\mu)U^H_\mu(n + a_\mu)U^H_\nu(n) \approx \mathcal{H}(A) := \text{Pexp}(i \int_{\partial f} A), \quad (11)$$

where $\partial f$ denotes the boundary of the plaquette $f$. In LGT, this quantity is
known as the Wilson loop. Moreover, we approximate the curvature as

$$F^f_{\mu\nu} \approx U_f - \mathbb{I}. \quad (12)$$

Finally, the LGT action is defined as

$$S_{LGT} = \beta \sum_f \frac{1}{4} \text{tr} [(U_f - \mathbb{I})(U_f - \mathbb{I})^H] = \beta \sum_f 1 - \frac{1}{4} \text{tr}(U_f + U_f^H), \quad (13)$$
where $\beta$ is related to the coupling constant by $\beta = 4/e^2$. A discrete gauge transformation is associated with a choice of $G(n) \in SU(2)$ for each node $n$. Each link variable then transforms as

$$U_\mu(n) \mapsto G(n)U_\mu(n)G(n + a_\mu)^{-1}. \quad (14)$$

By the cyclic invariance of the trace, the action $S_{LGT}$ is discretely gauge invariant.

**Remarks.** The LGT action can be viewed as a mass lumped FEM action, and this observation is useful to have in mind when we construct the simplicial analogue. In the FEM setting, the gauge potential is assumed to be a lowest order curl-conforming Ndlec element in 4d on hypercubes, with one dimension representing time [19]. The degree of freedom associated to such a gauge potential at an edge $e$ from $n$ to $n + a_\mu$ is

$$A_e = \int_n^{n+a_\mu} A = hA_\mu(n + \frac{1}{2}a_\mu).$$

The parallel transport operator is as in equation (10), i.e. $U_\mu(n) = \exp(iA_e)$. Then, the holonomy is approximated as in equation (11), the curvature as in equation (12), and one considers $U_f - 1$ as the components of the two-form

$$\sum_f (U_f - 1)\omega_f,$$

where $\{\omega_f\}$ are the Ndlec basis two-forms. The FEM action associated to such a two form is

$$S := \frac{\beta}{2} \sum_{f,f'} M_{ff'} \text{tr} [(U_f - 1)(U_{f'} - 1)^H], \quad M_{ff'} := \int_M \omega_f \cdot \omega_{f'},$$

where $M_{ff'}$ is called the mass matrix, and $(\cdot)$ denotes the scalar product of alternating forms w.r.t. the metric. The mass matrix is not diagonal, which means that the discrete curvature at different faces interact. This again implies that the action is not discretely gauge invariant. However, by diagonalizing the mass matrix using numerical quadrature, this action reduces to the LGT action, equation (13). The diagonalization procedure can also be shown to be numerical consistent in the sense of approximation theory [22].

### 2.3. Simplicial gauge theory

In this section we construct the discretely gauge invariant simplicial gauge theory (SGT) action on a simplicial complex, as defined in appendix Appendix [A]. The construction is the simplicial analogue of the FEM action described above, including additional parallel transport operators to make it discretely gauge invariant.
The curvature associated to the temporal and spatial faces is defined exactly as in LGT. In the notation of appendix Appendix A, consider a temporal and spatial face

\[ f_t(\tau) := \{i, j, j + \Delta t, i + \Delta t\} \]

\[ f(\tau) := \{i, j, k\} \]

(15)

where \(i\) denotes node \(i\) at time \(\tau\). The time dependency will from here on often be suppressed, unless confusion can arise. The spatial and temporal holonomies associated to these faces, induced by the gauge potential, are approximated as

\[ U_{f_t}(i) = U(i, j)U(j, j + \Delta t)U(j + \Delta t, i + \Delta t)U(i + \Delta t, i) \]

\[ U_f(i) = U(i, j)U(j, k)U(k, i) \]

(16)

where the arguments \(i\) and \(i\) are included to indicate where the holonomy is located, and the parallel transport operators are defined exactly as in LGT, i.e. equation (10). We observe that the holonomies located at different nodes are related through the formulas

\[ U_{f_t}(i + \Delta t) = U(i + \Delta t, i)U_{f_t}(i)U(i, i + \Delta t) \]

\[ U_f(j) = U(j, i)U_f(i)U(i, j) \]

which give formulas for parallel transport of curvature. Hence, we have defined the curvature associated to the temporal and spatial faces in our 4d mesh. The distinguished point of \(f\) and \(f_t\), i.e. the location of their holonomy, are denoted \(\dot{f}\) and \(\dot{f}_t\) respectively. Note that under a discrete gauge transformation, the parallel transport operators are transformed as in LGT, i.e.

\[ G(i)U(i, j)G(j)^{-1} \]

for \(G(i) \in SU(2)\) for each vertex \(i\).

As in LGT the curvature is approximated as

\[ F_t \approx U_{f_t} - \mathbb{1} \]

\[ F_s \approx U_f - \mathbb{1} \]

(17)

considered as components of the two-forms

\[ \sum_{f_t} (U_{f_t} - \mathbb{1}) \Lambda_{f_t} \]

\[ \sum_f (U_f - \mathbb{1}) \Lambda_f \]

where the \(\Lambda\) are basis functions as described in appendix Appendix A. The associated FEM action is \(S = S_t + S_s\), where the temporal part is

\[ S_t = \frac{\beta}{2} \mathfrak{R} \sum_{f_t, f_t'} M_{f_t, f_t'} \text{tr} [(U_{f_t} - \mathbb{1})(U_{f_t'} - \mathbb{1})^H] \]

\[ M_{f_t, f_t'} := \int_M \Lambda_{f_t} \cdot \Lambda_{f_t'} \]

(18)
and the spatial part is

$$S_s = \frac{\beta}{2} \Re \sum_{f, f'} M_{ff'} \text{tr} \left[ (U_f - 1)(U_{f'} - 1)^H \right], \quad M_{ff'} := \int_{\mathcal{M}} \Lambda_f \cdot \Lambda_{f'},$$

where $\beta = 2/e^2$. Note that we have suppressed the dependency of $S$ on $A$.

Again, $M_{ff'}$ and $M_{ff'}'$ are called mass matrices that depend on the details of the mesh, and are described more in detail in appendix A. As pointed out in the discussion about the FEM formulation of LGT, the mass matrices are not diagonal. This implies that the action is not discretely gauge invariant. However, this can be resolved by parallel transport of curvature. The temporal and spatial part of the action, $S_t$ and $S_s$, are now treated separately.

The temporal part. Let $f_t(\tau)$ and $f'_t(\tau)$ be two temporal faces. We now use some properties of the basis functions, which are explained in appendix A. Since the temporal basis face functions ($\Lambda_{f_t}$) are piecewise constant in time, the interactions between the temporal curvature occur only at coinciding time intervals. Also, by properties of the edge basis functions ($\lambda_e$), which define the temporal basis face functions, we can connect the curvature at $f_t$ with the curvature at $f'_t$ by parallel transport along at most one edge. Thus, we connect the curvatures by parallel transport along the connecting edge $e = \{\dot{f}_t, \dot{f}'_t\}$ of their distinguished points. In other words, we approximate the temporal part of the action by

$$S^t_{SGT} := \frac{\beta}{2} \Re \sum_{f_t(\tau), f'_t(\tau)} M_{f_t(\tau), f'_t(\tau)} \times \text{tr} \left[ U(\dot{f}'_t, \dot{f}_t(\tau)) (U_{f_t(\tau)} - 1) U(\dot{f}_t, \dot{f}'_t(\tau')) (U_{f'_t(\tau')} - 1)^H \right].$$

The spatial part. Let $f$ and $f'$ be two spatial faces of a tetrahedron $T$. The curvature associated to the face $f$ at time $\tau$ will interact with the curvature associated to the face $f'$ not only at time $\tau$, but also at times $\tau \pm \Delta t$, since the facial basis functions are piecewise affine in time. Thus, to connect the curvature at $f(\tau)$ with the curvature at $f'(\tau')$ we must parallel transport in both space and time. Thus, we replace

$$(U_{f(\tau)} - 1)(U_{f'((\tau'))} - 1)^H$$

by

$$U(\dot{f}(\tau), \dot{f}(\tau))(U_{f(\tau)} - 1)U(\dot{f}(\tau), \dot{f}(\tau'))U(\dot{f}'(\tau), \dot{f}'((\tau')))(U_{f'(\tau')} - 1)^H U(\dot{f}'(\tau'), \dot{f}'(\tau'))$$

in the FEM action (19). In words, we first parallel transport the curvature associated to $f$, located at the vertex $\dot{f}(\tau)$ to the vertex $\dot{f}'(\tau)$ along the edge $e = \{\dot{f}(\tau), \dot{f}'(\tau)\}$. Then we parallel transport it in the temporal direction from
\[ \dot{f}'(\tau) \text{ to } \dot{f}'(\tau'). \] So, we approximate the spatial part of the action as

\[ S_{SGT}^s := \frac{\beta}{2} \mathbb{R} \sum_{f(\tau), f'(\tau')} M_{f(\tau), f'(\tau')} \text{tr} \left[ U(\dot{f}'(\tau), \dot{f}(\tau)) (U_{f(\tau)} - 1) U(\dot{f}(\tau), \dot{f}'(\tau)) \right. \]
\[ \times U(\dot{f}'(\tau), \dot{f}'(\tau')) (U_{f'(\tau')} - 1)^H U(\dot{f}'(\tau'), \dot{f}'(\tau)) \right]. \tag{21} \]

The simplicial gauge theory action is then defined as

\[ S_{SGT} := S_{SGT}^t + S_{SGT}^s, \tag{22} \]

and by the cyclic invariance of the trace, this action is discretely gauge invariant.

A companion paper [22] contains more details about this construction, as well as mathematical proofs of consistency with the continuous action (5) in the sense of approximation theory.

3. Computer simulation

For our SGT computer simulations, we chose the euclidean cubic domain \( M = [0,1]^4 \subset \mathbb{R}^4 \) with periodic boundary conditions. We simulated the pure gauge SGT action [22] in temporal gauge on a simplicial lattice with the gauge group \( SU(2) \). Choice of gauge is not necessary, but it does simplify the algorithm slightly, since all temporal edge matrices then reduce to the identity.

The spatial lattice was constructed using a cubic arrangement of \( N^3 \) identical building block cubes of size \( h^3 \), each consisting of six tetrahedra as shown in figure [1]. The resulting spatial mesh was repeated at \( N \) consecutive time steps to form a cubic domain of physical volume \( (hN)^4 \). As described above, each spatial edge is part of two temporal square-shaped faces, going forward and backward in time.
The SGT action employs parallel transport matrices in order for gauge invariance to be respected. By defining the distinguished points of all spatial and temporal faces to coincide for as many pairs of faces as possible, we only need the parallel transport matrices for terms in the action involving pairs of temporal faces with no common nodes. More details regarding the exact computer implementation are given in appendix Appendix C.

3.1. Convergence of the action

In order to check the continuum limit of the discrete action, we examined four different gauge field configurations for which the exact continuum value $S_{\text{cont}}$ of the action is calculable. We did numerical calculations for square meshes with $N = 4, 8, 16, 32$ in order to observe convergence of the numerical values towards the exact values. By the estimates in [22] we expect that the error be of second order in the lattice constant $h$. We used the following gauge field configuration cases:

1. Gauge field oriented towards the $x$-direction in space and towards $t^3$ within $su(2)$, with a sinusoidal $t$-dependence. The only nonzero component of the gauge field $A$ is

$$A^3_x(t, x, y, z) := \frac{e}{2\pi} \sin(2\pi t), \quad S = 1.$$  

2. Gauge field oriented towards the $y$-direction in space and $t^3$ within $su(2)$, with a sinusoidal $x$-dependence. The nonzero component of the gauge field in this case was

$$A^3_y(t, x, y, z) := \frac{e}{2\pi} \sin(2\pi x), \quad S = 1.$$  

3. A case with two nonzero components,

$$A^1_x := \frac{e}{2\pi} \sin(2\pi y), \quad A^2_y := \frac{e}{2\pi} \sin(2\pi x), \quad S = \frac{1}{2} + \frac{e^2}{8(2\pi)^4}.$$  

4. A constant field that only contributes to the nonlinear term in the field strength,

$$A^1_x := \sqrt{e}, \quad A^2_y := \sqrt{e}, \quad S = \frac{1}{2}.$$  

In order to provoke a sizable nonlinear contribution case 3, we chose a small $\beta = 2/e^2 = 1/5$. The link matrices needed to evaluate the SGT action are calculated from these gauge fields by means of the exponential map (10).

The results are displayed using double logarithmic plots in figure 2 for traditional Wilson action LGT as well as the SGT results. As expected from the estimates in [22], in all cases the relative error behaves as

$$\text{Relative error} \sim Ch^2,$$

as determined by extracting the linear coefficient of the second order polynomial fits shown in the figures. Note that while the convergence exponent of $h$ is the
same in all cases, the prefactor $C$ is smaller in the SGT cases involving time-independent fields, due to its finer spatial discretization for the same $N$. Where time-dependence is involved, the errors coincide since the time-discretization we have chosen for this SGT simulation is of the same quality as for the LGT simulation.

3.2. Quantum field simulation

Analogous to the traditional lattice QCD simulations, we performed parallel $SU(2)$ quantum field theory Monte Carlo simulations for $N = 8$. In this case, the edge matrices are sampled directly without reference to a gauge field and lattice constant value. Therefore, the physical size of the simulation domain is unknown prior to experimental comparisons. All dimensional observable quantities are automatically calculated in units of powers of the lattice constant $h$.

As is customary, it is a Monte Carlo simulation using the Metropolis algorithm to generate a Markov chain of gauge field configurations that are distributed according to the Boltzmann weight $\exp(-S)$. Each Monte Carlo step involves randomization of some edge $SU(2)$ matrices, which is done by multiplication of a small $\mathfrak{su}(2)$ algebra matrix, together with a Metropolis step for acceptance/rejection of the update. The algorithm adapted itself to drive the MC acceptance rate towards $1/2$. Monte Carlo convergence tests were done and high quality error estimates were made using data blocking [23]. In addition, convergence was verified subjectively by inspection of the time series for observable values with their accompanying distributions, as well as time series for cumulative averages. The data blocking error estimates were found to be smaller than the displayed data points in all the plots.

We simulated at different values of $\beta$, at each of which we measured the average action density $S/N^4$, and a list of different Wilson loops shown in figure

Figure 2: The relative error of the action versus the number of lattice sites per side $N$, for the actions 1, 2, 3, 4 described in section [3.1] The squares are the simulation data points and the solid lines are the second order polynomial fits. Errors are proportional to $h^2$ in all cases.
all of which are gauge-invariant quantities. For each Wilson loop shape, we average over all possible loop positions, as well as loop orientations in the $xy$, $yz$ and $zx$ planes. For a given closed path $C$, the corresponding Wilson loop variable for gauge group $SU(n)$ is defined as

$$W_C := \frac{1}{2} \Re \text{tr} \prod_{e \in C} U_e,$$

which involves an ordered product of the edge matrices $\{U_e\}$ along the path $C$.

Expectation values for any observable quantity $O$, e.g. the action density $S/N^4$ or a Wilson loop $W_C$, is given by

$$\langle O \rangle = \frac{1}{Z} \left( \prod_e dU_e \right) O \exp(-S),$$

where the partition function $Z$ is defined by

$$Z := \int \left( \prod_e dU_e \right) \exp(-S).$$

The integration measure involved in these expressions is a product of the normalized Haar integration measure for each edge group element in the mesh. Note that the normalized Haar measure satisfies

$$\int_G dU = 1.$$

To accompany these measurements, the strong (small $\beta$) and weak (large $\beta$) coupling asymptotic behaviour were calculated in appendix B using methods described in [6]. At strong coupling, this involves various group integrals, while at weak coupling it suffices to use a thermodynamic analogy to determine the limiting behaviour.

The simulated results for the action density and Wilson loops are displayed in figure 4. In figure 4a we can see the characteristic and nontrivial behaviour.
Figure 4: Plots showing the $\beta$-dependency of (a) the average action density $\langle S/N^4 \rangle$ and (b) the various Wilson loops $\langle W \rangle$ from figure 3. Solid squares are data points and solid lines are linear interpolations. The strong and weak coupling asymptotes calculated in Appendix B are included for the action density and the elementary triangular loop. Monte Carlo errors are smaller than the data points.

in the medium coupling range $\beta \in (1, 3)$. This coincides qualitatively with LGT simulations [23]. Only qualitative, not exact, agreement is expected, since the physical lattice constant will differ in each type of simulation. Compared to LGT simulations, the behaviour at small $\beta$ deviates more from linearity due to the nonlinear aspects of the SGT action. In this region, the actions do not approximate the continuum action, and differences between discrete actions are unphysical.

The Wilson loops in figure 4b show the same qualitative behaviour as do LGT simulation results, and approaches the calculated asymptotes nicely. Also here, the behaviour is less linear at small $\beta$ for the same reason as stated above. The typical strong suppression of the Wilson loops as functions of loop area is reproduced, as expected from the area law behaviour that indicates confinement.

4. Conclusions

We have implemented the general SGT action on a particular simplicial mesh, and performed Monte Carlo quantum field theory simulations that show sensible results that are qualitatively consistent with standard LGT simulations, as must be the case for this initial proof-of-concept implementation.

We expect that this method will lend itself nicely to the use of mesh refinement within quantum QCD simulations, and that this will lead to opportunities of novel applications using nontrivial mesh structures, e.g. in the vicinity of gluon flux tubes as mentioned in the introduction.

The nondiagonal nature of the action increases the amount of computer work in the Metropolis step after each proposed update. However, since the number
of interactions for each elementary face is finite, the scaling at large meshes for this model will be the same as for traditional QCD. There might be possibilities of real-time adaptive diagonalization, thereby increasing the algorithm efficiency throughout the initial part of the simulation.

Appendix A. Simplicial complex, finite elements and mass matrices

Consider a collection of vertexes, edges, faces, tetrahedra in 3d space. These elementary objects are called simplexes, and the collection of these a simplicial complex $T$. For any $k$-dimensional simplex $T_k$ for $1 \leq k \leq 3$, the boundary $\partial T_k$ is a union of $(k - 1)$-dimensional simplexes. Consult [25, Section 5.1] for a precise definition. In our construction, we assume that this spatial simplicial complex spans the spatial domain $S$. The vertexes, edges, faces, and tetrahedra according to dimension, and are labeled $i$, $e$, $f$, and $T$ respectively. The symbol $T$ will be used for simplexes of any dimension.

In order to expand this to a 4d spacetime simplicial complex $T$, consider a uniform time-discretization with a time-spacing $\Delta t$. The simplicial complex $T$ is then repeated at each discrete time step value $\tau$. For each such $\tau$, we define additional simplexes for our $T$ by extruding each simplex of $T$ along the time interval $[\tau, \tau + \Delta t]$. As the basic building block in classical 3d FEM theory is a tetrahedron $T$, the basic building block in this extended FEM version is $T \times I_\tau$, where $I_\tau = [\tau, \tau + \Delta t]$, i.e. a time-extrusion of a tetrahedron. Temporal edges are generated by extruding 3d vertices, and temporal faces by extruding 3d edges.

The space of Whitney k-forms on $T$ ($W^k(T)$) is denoted $W^k_k(T)$, with canonical basis $(\lambda T)$, $T$ ranging over the set of $k$-dimensional simplexes in $T$ [20]. The 0-forms $\lambda_1$ are the barycentric coordinate maps for each vertex $i$. In other words, it is the piecewise affine map taking the value 1 at the vertex $i$ and 0 at other vertices. For an edge $e = \{i, j\}$, with orientation $i \rightarrow j$, the associated Whitney 1-form is defined by

$$\lambda_e := \lambda_{ij} := \lambda_i \nabla \lambda_j - \lambda_j \nabla \lambda_i. \tag{A.1}$$

For a face $f = \{i, j, k\}$, whose orientation is $i \rightarrow j \rightarrow k$, the associated Whitney 2-form is defined by

$$\lambda_f := \lambda_{ijk} := 2 (\lambda_i \nabla \lambda_j \times \nabla \lambda_k + \lambda_j \nabla \lambda_k \times \nabla \lambda_i + \lambda_k \nabla \lambda_i \times \nabla \lambda_j). \tag{A.2}$$

In the 4d spacetime FEM setting, these basis $k$-forms are extended to be piecewise affine in time and are denoted $(\Lambda_{T(\tau)})$, i.e.

$$\lambda_T \rightarrow \Lambda_{T(\tau)} = \lambda_T \otimes P^t_1,$$

where $P^t_1$ denotes polynomials in the time variable of degree at most one, and $T(\tau) := (\tau, T)$ denotes the spatial simplex $T$ at temporal node $\tau$. More precisely, $\Lambda_{T(\tau)}$ is the piecewise affine function in time, taking the value $\lambda_T$ at $\tau$ and 0 at
the other temporal nodes. In addition, we define temporal basis edge and face functions.

To every vertex $i$ in the spatial mesh there are temporal edges $e_t(\tau) = \{i_\tau, i_{\tau+\Delta t}\}$, where $i_\tau := i(\tau)$. The temporal basis edge function attached to $e_t(\tau)$ is then the piecewise constant function in time defined by

$$\Lambda_{e_t(\tau)}(t) = \begin{cases} 
\lambda_i \circ \pi \frac{1}{\Delta t} dt, & t \in [\tau, \tau + \Delta t] \\
0, & \text{otherwise}.
\end{cases}$$

where $\pi$ is the canonical projection onto the space $S$,

$$\pi : \mathbb{M} = \mathbb{R} \times S \to S,$$

and $dt$ is the standard basis one-form in the temporal direction.

To every spatial edge $e$ there are corresponding temporal faces $f_t(\tau) = e \times I_\tau$. The temporal basis face function attached to $f_t(\tau)$ is then the piecewise constant function in time defined by

$$\Lambda_{f_t(\tau)}(t) = \begin{cases} 
\lambda_e \circ \pi \wedge \frac{1}{\Delta t} dt, & t \in [\tau, \tau + \Delta t] \\
0, & \text{otherwise}.
\end{cases}$$

In addition to these basis functions, we must define mass matrix elements. Let $m_{TT'}$ denote the classical 3d mass matrices for spatial Whitney elements

$$m_{TT'} = \int_S \lambda_T \cdot \lambda_{T'},$$

where $T, T'$ are $k$-dimensional simplexes, and $(\cdot)$ denotes the scalar product of alternating forms.

In the definition of the SGT action we use the generalization

$$M_{T(t)T'(\tau)} = \int_{\mathbb{M}} \Lambda_{T(t)} \cdot \Lambda_{T'\tau}.$$

This generalization can be expressed through the classical mass matrices by performing the time integration explicitly. Thus, let $T$ be a spatial tetrahedron and $I_\tau = [\tau, \tau + \Delta t]$. Considering now only this time interval, the piecewise affine function taking the value 1 at time $\tau$ and 0 at time $\tau + \Delta t$ is given by

$$p_\tau(t) = 1 - \frac{t - \tau}{\Delta t}.$$

The analogous function for the temporal node $\tau + \Delta t$ on the same time interval is given by

$$p_{\tau+\Delta t}(t) = \frac{t - \tau}{\Delta t}.$$

Restricted to the basic building block $T \times I_\tau$, we therefore get

$$M_{f(\tau)f'(\tau)}(T \times I_\tau) = \int_{T \times I_\tau} \Lambda_{f(\tau)} \cdot \Lambda_{f'\tau} = \int_{I_\tau} \int_T p_\tau^2 \int_T \lambda_f \cdot \lambda_{f'} = \frac{1}{3} \Delta t m_{ff'}(T),$$

15
\[
M_{f(\tau)f'(\tau+\Delta t)}(T \times I_t) = \int_{T \times I_t} \Lambda_{f(\tau)} \cdot \Lambda_{f'(\tau+\Delta t)} = \\
= \int_{I_t} p_{\tau}p_{\tau+\Delta t} \int_T \lambda_f \cdot \lambda_{f'} = \frac{1}{6} \Delta tm_{ff'}(T),
\]

\[
M_{f(\tau+\Delta t)f'(\tau+\Delta t)}(T \times I_t) = \int_{T \times I_t} \Lambda_{f(\tau+\Delta t)} \cdot \Lambda_{f'(\tau+\Delta t)} = \\
= \int_{I_t} p_{\tau+\Delta t} \int_T \lambda_f \cdot \lambda_{f'} = \frac{1}{3} \Delta tm_{ff'}(T).
\]

Similarly, the mass matrix element corresponding to the temporal face basis is given by

\[
M_{f_t(\tau)f'_t(\tau)}(T \times I_t) = \int_{T \times I_t} \Lambda_{f_t(\tau)} \cdot \Lambda_{f'_t(\tau)} = \frac{1}{\Delta t} \int_T \lambda_e \cdot \lambda'_{e'} = \frac{1}{\Delta t} m_{ee'}(T).
\]

**Appendix B. Strong and weak coupling limits**

**Appendix B.1. Strong coupling limit**

Here we will show some details regarding the calculation of the strong coupling limits of the elementary triangular Wilson loop. We will use the following integrals over \(SU(2)\) group space \[6\]

\[
\hat{d}UU^{\alpha\beta} = 0, \quad \hat{d}UU^{\alpha_1\beta_1}U^\dagger_{\beta_2\alpha_2} = \frac{1}{2} \delta^{\alpha_1\alpha_2} \delta^{\beta_1\beta_2}, \quad \int dUU^{\alpha_1\beta_1}U^\dagger_{\alpha_2\beta_2} = \frac{1}{2} \epsilon^{\alpha_1\alpha_2\beta_1\beta_2}, \tag{B.1}
\]

where the Greek symbols are matrix indices.

In this calculation, the Wilson loop encircles an elementary spatial triangular plaquette \(P_t\) at time \(t\). We denote this Wilson loop by \(W_{P_t}\). By equation (23), it is given by

\[
W_{P_t} := \frac{1}{2} \text{tr} \left( U_a U_b U_c \right),
\]

where the plaquette \(P_t\) is encircled cyclically by the \(SU(2)\) edge matrices \(U_a, U_b\) and \(U_c\). Due to our choice of distinguished points and plaquette orientations, the spatial SGT action is given by

\[
S = \frac{\beta}{2} \sum_{f,f'} M_{ff'} \text{tr} \left( U_f U_{f'}^H - U_f - U_{f'}^H + 1 \right),
\]
where the sum extends over all spatial faces at all times. Since we are interested in small $\beta$, consider a first order truncated Taylor expansion of the exponential in equation (24), i.e.

$$\langle W_{P_t} \rangle \approx -\frac{\beta}{4Z_{\beta}} \left( \prod_e dU_e \right) \Re \text{tr} \left( U_a U_b U_c \right) \sum_{f,f'} M_{ff'} \text{tr} \left( U_f U_{f'}^H - U_f - U_{f'}^H + 1 \right).$$

By the properties of the $SU(2)$ integration measure, terms involving integration over odd powers of link matrices vanish. Therefore, nonvanishing contributions to the integral only come from terms where either $f$ and/or $f'$ coincide with the plaquette $P_t$. The $U_f U_{f'}^H$ doesn’t contribute. Indeed, if either $f$ or $f'$ differ from $P_t$, we such a term includes an integral over a single power, which vanishes. If on the other hand $f = f' = P_t$, we have $U_f U_{f'}^H = 1$ which again leads to an integral over a single power and thus vanishes. This is also the case for the constant term in the parenthesis.

We are left with

$$\langle W_{P_t} \rangle \approx \frac{\beta}{4Z_{\beta}} \Re \int \left( \prod_e dU_e \right) \text{tr} \left( U_a U_b U_c \right) \sum_{f,f'} M_{ff'} \text{tr} \left( U_f + U_{f'}^H \right),$$

where we have moved the real part operator $\Re$ outside of the integral. Contributions only come when at least one of $f,f'$ coincide with $P_t$. Therefore, by the properties of the particular mesh we have constructed,

$$\langle W_{P_t} \rangle \approx \frac{\beta}{4Z_{\beta}} \left( M_{P_t P_t} + M_{P_t P_{t+1}} + M_{P_t P_{t-1}} \right) \times$$

$$\times \Re \int \left( \prod_e dU_e \right) \text{tr} \left( U_a U_b U_c \right) \text{tr} \left( U_{P_t} + U_{P_t}^H \right).$$

Using $U_{P_t} := U_a U_b U_c$ and the $SU(2)$ integration formulas (B.1), we get

$$\langle W_{P_t} \rangle \approx \beta \left( M_{P_t P_t} + M_{P_t P_{t+1}} + M_{P_t P_{t-1}} \right) = \frac{2}{3} \beta,$$

where we have used $Z \approx 1$ for small $\beta$. The last equality follows from the particular mass matrix element values produced by our choice of simplicial lattice.

A similar calculation, only slightly more involved because several faces are involved, can be performed to determine the strong coupling limit of the action. Approximations of higher order in $\beta$ can be found by including higher order terms in the Taylor expansion of the exponential.

**Appendix B.2. Weak coupling**

In order to determine the weak coupling limit of the action density, we simple follow a thermodynamic analogy described in [6]. At large $\beta$, the system is described well by a gaussian partition function approximation. This corresponds to a free theory, and we can find the weak coupling limit of the action by
distributing an amount $kT/2 = 1/2\beta$ of energy among all the degrees of freedom in the theory. We have seven edges for each building block cube, each of which contributes three degrees of freedom (the number of generators of $SU(2)$). To obtain the action, we multiply by $\beta$, which results in

$$S_{SGT} \rightarrow \beta \times \frac{1}{2\beta} \times 7 \times 3 = \frac{21}{2} N^4, \quad \text{as } \beta \to \infty. \quad (B.2)$$

This result can be used to determine the same limit of the triangular Wilson loop in the $\alpha\beta$-plane. We have

$$\langle W_1 \rangle = 1 - \frac{a^4}{16} \langle \text{tr}(F_{\alpha\beta}^2) \rangle,$$

where there is no sum over the spacetime indices. The antisymmetric field strength has six independent spacetime components. By the equipartitioning of the euclidean energy among these degrees of freedom, we have

$$\langle \text{tr}(F_{\alpha\beta}^2) \rangle = \frac{1}{6} \langle \text{tr}(F_{\mu\nu}F^{\mu\nu}) \rangle = \frac{2g^2}{6} \langle S_{SGT} / N^4 \rangle = \frac{42g^2}{12}.$$

Now using $\beta = 2/g^2$, we get

$$\langle W_1 \rangle = 1 - \frac{21}{48\beta}. \quad (B.3)$$

**Appendix C. Computer implementation**

Our computer implementation of the simplicial lattice and accompanying SGT action consists of object-oriented C++ code, using MPICH2 [26] for parallelization, running on a quadruple CPU run-of-the-mill modern workstation computer. The data structures involved are reminiscent of what is used in implementations of the finite element method. This involves different types of mass matrix and connectivity information for elements of the simplicial mesh. The parallelization consisted of running independent simulations on each node, and averaging the results. We used the yarn2 algorithm from the TINA pseudorandom number generator [27], which is designed for use in parallelized algorithms. Although the edge matrix randomization appeared to perform stably enough for our purposes, we regularly did projections of the edge matrices onto $SU(2)$ as a precautionary measure.
