Management of an Unusual Intranasal Foreign Body Abutting the Cribiform Plate: A Case Report and Review of Literature

Department of Otolaryngology—Head and Neck Surgery, Icahn School of Medicine at Mount Sinai, New York, NY, USA.

ABSTRACT: A 35-year-old man with history of schizophrenia presented 3 weeks after placing a screw in his right nostril. Initial imaging showed a screw in the right ethmoid sinus with the tip penetrating the right cribiform plate. On exam, the patient was hemodynamically stable with purulent drainage in the right nasal cavity but no visible foreign body. While most nasal foreign bodies occur in children and are generally removed at the bedside, intranasal foreign bodies in adults tend to require further assessment. The foreign body in this case was concerning for skull base involvement and the patient was brought to the operating room (OR) with neurosurgery for endoscopic sinus surgery (ESS) and removal of foreign body. The screw was removed and the patient recovered with no signs of cerebrospinal fluid (CSF) leak postoperatively. Any concern for skull base or intracranial involvement should call for a full evaluation of the mechanism of injury and intervention in a controlled environment.

KEYWORDS: Intranasal, foreign body, endoscopic, cribiform plate

INTRODUCTION

Intranasal foreign body is typically a common chief complaint among the pediatric population. In a review of all Emergency Department (ED) visits in a 5-year span, there were 6418 (3.2% of all visits) visits nationwide for management of nasal foreign bodies, only 214 (0.1%) of which were adults. The median age was 3 years. The majority of these patients were discharged from the ED, but certain foreign objects such as button batteries and sharp objects required further assessment. Due to the low incidence of nasal foreign bodies among adults with different mechanisms of injury (self-inflicted vs projectile), most literature reports individual cases. Here, we present a unique situation where an adult patient inserted a large screw into his ethmoid sinus that abutted the cribiform plate.

CASE REPORT

The patient was a 35-year-old male with history of schizophrenia and psychosis who reported that he inserted a screw inside his right nostril 3 weeks prior and presented with mild epistaxis and nasal congestion. He reported that he heard voices that told him to put the screw in his nose so that he could keep his job. He endorsed trying to push the screw in further, hoping it would fall out of his mouth. The patient was seen by his primary care physician in the past for foreign objects in his ears and nose. He once swallowed a part of a milk can and was seen by his primary care physician for management of nasal foreign body. He denied additional symptoms, including fever, nasal drainage, pain, or vision changes. On initial nasal endoscopy, there was purulent drainage along the floor of the right nasal cavity but no obvious foreign body visualized. Non-contrast computed tomography (CT) sinus confirmed the foreign body with dehiscence of anterior cranial fossa (Figures 1 and 2).

Upon arrival at our institution, CT angiography was obtained that did not reveal any intracranial vascular injury. He was started on intravenous (IV) vancomycin and ceftriaxone while cultures were sent and consulting teams from Neurosurgery, Psychiatry, and Infectious Disease were called. At the recommendation of the Infectious Disease service, ceftriaxone was continued until cultures resulted in methicillin-susceptible

Figure 1. Initial non-contrast CT sinus coronal view demonstrating intranasal foreign body displacing the cribiform plate. CT indicates computed tomography.
Staphylococcus aureus (MSSA) and Klebsiella. He remained stable during the course of the admission and was discharged on Augmentin 875 mg twice a day for 10 days.

The patient underwent an elective right maxillary antrostomy, total ethmoidectomy, and frontal sinusotomy with removal of anterior skull base foreign body. Synechia between the septum and lateral nasal wall was removed before locating the screw, which was covered in a plastic sheath. The screw was displaced inferiorly away from the skull base and maneuvered out of the nasal cavity. Other foreign material was cleared from the nasal cavity and close inspection revealed no visible cerebrospinal fluid (CSF) leak or skull base defect. Surgicel and Evicel tissue glue were applied and held up with Nasopore.

Postoperatively, patient appeared well but had diminished sense of smell. Repeat CT scan showed elevation of the skull base and no pneumocephalus (Figure 3). Postoperative magnetic resonance imaging (MRI) showed some leptomeningeal enhancement but no encephalocele (Figure 4). The patient did not demonstrate any sign of CSF leak. The patient was discharged on postoperative day 2 with oral antibiotics. He was last seen 6 months later with no complaints. There was synechia again noted between the septum and inferior turbinate. Ethmoid and frontal sinuses were patent, but the maxillary sinus opening was not visualized (Figure 5). The patient has since been lost to follow-up.

Discussion

Intranasal foreign bodies are common among the pediatric population. With adult patients, however, the mechanism and force of entry must be considered as there is a greater chance of violation of the skull base and possible CSF leak. In a review of the literature, there were 19 case reports of adult patients presenting with foreign bodies in the paranasal sinuses that were not caused by dental procedures, war-related injuries, or injury via an orbital entry (Table 1). Some foreign bodies were the result of accidents or explosions, while others were intentionally placed like in our case.

There were no obvious trends in preoperative imaging or approach for removal. Initial imaging included X-ray, CT, or both. No cases obtained an MRI prior to removal of the foreign object—MRI was likely contraindicated in most cases due to the risk of metallic foreign body migration. Some obtained MRI postoperatively as we did in our case. Decisions to go to the operating room (OR) depended on the stability of the patient and risks for complications such as infections or CSF leak.21 About half of the cases were endoscopic-assisted and most cases were done in the OR. Two cases required craniotomies for removal of foreign body.3,19 In 1 case, the patient could not tolerate bedside removal of an open safety pin with local anesthesia because of pain and the decision was made to remove the foreign body in the OR.18

Many reports of endoscopic removal of foreign bodies from adults have been made since the advancement of transnasal endoscopic surgery in the 1980s. Pagella et al22 demonstrated endoscopic retrieval of dental implants using trocars introduced superior and lateral to upper canine root. Dodson et al presented a case of a patient with schizophrenia that similarly placed multiple objects through the site of a molar extraction.15 Endoscopic retrieval of the objects in this case involved creating a larger skull base defect to retrieve a foreign body that penetrated the ethmoid roof.15

Complications of foreign bodies that violate the skull base include meningitis, brain abscess, CSF leak, neural compromise, and vascular injury. Complications of foreign bodies in the paranasal sinuses included chronic inflammation with disruption of ciliary clearance, cutaneous fistula, rhinolith formation, lead poisoning, and chronic pain.15,23,24 While foreign bodies (such as bullets) were usually left in soft tissue elsewhere in the body, Brinson et al24 argued for removal of foreign bodies in the paranasal sinuses due to the unique environment of the sinuses that presents a higher risk for infection. However, there were conflicting recommendations regarding the use of prophylactic antibiotics. One review found that most reported cases received antibiotics, but in our review of 19 cases, only 6 case reports discussed antibiotic use (Table 1).21

Yarlagadda et al21 conducted a retrospective review of 13 retained metallic foreign bodies in the sinuses and/or skull base over the course of 10 years and recommended removal for cases that are safely accessible and at risk for infectious complications be removed. Three of these patients had involvement of the skull base.
like our patient. All 3 of these patients experienced CSF leaks and 1 patient required skull base repair during removal of a nail from the clivus. Due to the unique nature of each injury and the scarcity with which they present, there was little evidence-based management for these injuries. However, Yarlagadda et al proposed an algorithm based on their 10-year retrospective review.

Conclusions
A skull base defect or intracranial involvement may not be apparent when evaluating a patient with an intranasal foreign object. Conversely, a patient with suggestive imaging may not have an alarming clinical presentation. In our case, the patient’s history and initial imaging were concerning for the need to repair a skull base defect. However, his ultimate outcome was more benign. It is important to use appropriate resources such as CT-angiogram and consulting services in carefully planning the management of these patients. Most patients will require operative exploration and possible repair of the skull base.
