The aim of this study was to evaluate mosquito abundance, species diversity, larval and adult population dynamics in seven lagoons integrated in the wetland coastal system of the Algarve, Portugal, in the summer of 2007, as well as the screening of these for West Nile virus (WNV). WNV has been isolated from mosquitoes in this region, in the summer of 2004, next to the putative area of infection of two linked human WN cases. Adult mosquitoes were collected with CDC traps baited with CO₂, and potential breeding sites were surveyed for immature stages. Morphological identification of 1,432 adult mosquitoes and 85 larvae revealed the presence of 10 species: Anopheles atroparvus, Anopheles algeriensis, Coquillettidia richardi, Culex modestus, Culex pipiens, Culex theileri, Culex univittatus, Culiseta longiareolata, Aedes caspius, and Aedes detritus. Adult mosquito peak densities were recorded in July, contrasting with null larval breeding in the same month in the surveyed biotopes. Most abundant species were C. pipiens (52%), C. theileri (29%), and A. caspius (11%). Lagoon Salgados and Quinta das Salinas, exhibited the highest similarity of culicid fauna, despite being most distant from each other. Female mosquitoes (1,249 specimens) screened by RT-PCR, did not reveal WNV products. However, previous detection of WNV activity in this area, susceptible to re-introductions, demands for continued vigilance.

Keywords: mosquitoes, wetlands, ecology, surveillance, WNV, Portugal

INTRODUCTION

Mosquitoes act as vectors in the transmission of human diseases, such as several arboviruses belonging to the genera Alphavirus, Flavivirus, and Bunyavirus (Lundström, 1999). West Nile virus (WNV) currently the most widely distributed arbovirus in the world, occurring on all continents except Antarctica, has been reported to occur in mosquitoes and to infect human and other vertebrates (Kramer et al., 2008). This virus was first isolated from the blood of a sick woman in the West Nile District of Uganda in 1937 (Smithburn et al., 1940).

In recent years human or animal, mainly enzootics involving horses, WNV disease in the Eastern Hemisphere have been reported mostly from areas in the Mediterranean Basin; in Algeria in 1994, Morocco in 1996 and 2003, Tunisia in 1997 and 2003, Romania in 1996 through 2000, Czech Republic in 1997, Israel in 1999 and 2000, Russia in 1999–2001 and 2003–2007, Hungary 2003–2008, southern France in 2003, 2003–2004, Italy in 1998, 2008–2009, Spain in 2008–2009, and Greece 2010–2011 (Murgue et al., 2001; Zeller and Schuffenecker, 2004; Hayes et al., 2005; Krisztalovics et al., 2008; Rossini et al., 2008; Barzon et al., 2009; Rizzo et al., 2009; Chaskopoulou et al., 2011; Danis et al., 2011a,b; Vázquez et al., 2011).

In Portugal epidemiologic surveys for West Nile detection in human and animal populations have been carried out since the 1970s revealing seroreactivity for this virus. However, the first WNV isolation from mosquitoes was reported in 1971 (Filipe, 1972). In the summer 2004 two linked WNV cases were reported in Irish tourists, acquired in the Algarve (Connell et al., 2004) after which WNV was isolated from mosquitoes in the same region (Esteves et al., 2005).

Throughout its worldwide distribution, WNV is maintained in nature by enzootic cycles between ornithophilic mosquitoes, predominantly Culex species, although other genera may also be vectors, and birds (Hayes et al., 2005). Mosquitoes can also act as bridge vectors transmitting WNV out of its natural cycle to accidental hosts, such as domestic animals, particularly horses, and humans (Rappole and Hubálek, 2003; Linke et al., 2007; Kramer et al., 2008).

There are two important periods for pathogen introduction that correspond to the biannual bird migration. The first, during spring, when birds fly from Africa and can introduce pathogens in the North hemisphere especially in Mediterranean wetlands as well as in other countries from Europe. The second period, in autumn, when birds return to Africa, may carry pathogens from Northern to Southern Europe (Jourdain et al., 2007). WNV has been isolated from actively migrating birds (Malkinson et al., 2002). In European regions WNV cases occur in late summer and early fall months, when mosquito populations are at their highest densities. WNV outbreaks have occurred at urban sites near wetlands where migratory birds, mosquitoes, and humans are concentrated (Rappole et al., 2000).
Climate changes can influence significantly vector-borne disease transmission, as insects are very sensitive to meteorological conditions, namely temperature and humidity. Warmer weather and high precipitation may lead to sudden increases of mosquito populations, due to abundant larval habitats and climatic favorable conditions. Warmer weather would also influence people’s behavior, leading them to spend more time outdoors. Outdoor activities, associated or not with tourism, can lead to higher exposure of humans to mosquito bites, and consequently to the transmission of mosquito borne diseases (Morgan, 2006). The ecological understanding of mosquito vectors of arboviruses is an important contribution of the surveillance regarding the risks for public health and mosquito control programs (White, 2001; Rydzanicz and Lonc, 2003; Medlock et al., 2006).

Due to its geographic localization and favorable climate, the Algarve province combines several conditions that can lead to the emergence and re-emergence of mosquito borne diseases. The presence of wetlands and lagoons, used by migratory birds can favor new viral introductions and the presence and abundance of mosquito populations can maintain viral enzootic cycles. This kind of water collections provide suitable breeding sites to some mosquito species reported as vectors of WNV (Medlock et al., 2006). The Algarve is a well known touristic place, with thousands of visitors every year.

The goals of our study included the study of the abundance and diversity of mosquitoes in the vicinity of several water collections, lagoons, of the Algarve used by migratory birds, as well as screening those mosquitoes for the presence of WNV.

**MATERIALS AND METHODS**

**STUDY AREA**

The study took place during the summer months of 2007, from June to September, in seven lagoons near the coastal line, in the province of the Algarve, southern Portugal, next to four localities, within a maximum distance of 30 km (Figure 1): (1, a) Lagoon Salgados (N37°5’53.33’’; W8°20’3.61’’), Pêra; (2, b) Lagoon Nova (N37°5’29.78’’; W8°8’33.28’’) and (2, c) Lagoon Antiga (N37°5’48.03’’; W8°8’57.98’’W), Vilamoura Natural Park, Vilamoura; (3, d) Lagoon Almargem (N37°6’8.07’’; W8°21’15.97’’), Quarteira; (4, e) Lagoon Dunas Douradas (N37°2’42.6’’; W8°3’8.4’’); (3, f) Lagoon Garrão (N37°2’42.6’’; W8°2’32.6’’) and Quinta das Salinas (N37°2’15.1’’; W8°2’1.3’’); (3, g) Garrão.

Some of these lagoons are referenced as regions of high diversity of wildlife including the presence of more than a hundred bird species. Due to this, and in particularly the Salgados lagoon was included in the national IBAs (PT035 Important Bird Area – 149 ha) being one of the more important wetlands in the Algarve, gaining national, and even international, interest, for some bird species, such as the *Porphyrio porphyrio* (Purple Swamphen) and *Aythya nyroca* (Ferruginous Duck; CCDR, 2007).

Algarve provides a wide range of outdoor activities, namely bird watching, fishery, aquaculture, and salt-works. Climate in the Algarve may be considered Mediterranean Csa type according to the Köppen–Geiger classification. For the interval 1971–2000, monthly average temperature varies from 16°C in January–December to 28°C in July–August (mean average 17°C, maximum...
After a centrifugation (896 × g), adult mosquitoes were triturated on a vibrator for 30 s with glass beads. Following reverse transcriptase, 5 μl of cDNA was transferred to 45 μl of a PCR mix containing 5 μl Taq buffer (1.75 μM MgCl2, 5 μM dNTP’s, 30 μl ddH2O, 0.5 μM Taq, and 1.25 μl of each primer, cFD2 (5′-GTGTCCCGCGGCTGTGCAGC-3′) and MAMD (5′-AACATGAGGGRAARGARGAAR-3′) in the first round (Scaramozzino et al., 2001) and FS 788M (Esteves et al., 2005) for the second. The thermal cycling profile consisted on 15 min at 94˚C, three initial cycles of 60 s at 94˚C, 60 s at 52˚C, and 60 s at 72˚C, followed by 40 cycles of 30 s at 94˚C, 30 s at 56˚C, and 30 s at 72˚C. The amplifications products were analyzed on agarose gels (1.5 or 2% for a better resolution) containing ethidium bromide.

RESULTS

ADULTS

A total of 1,432 adult mosquitoes were caught in the seven surveyed lagoons, between June and September 2007. Mosquito abundance, mean mosquito density per CDC trap, was lowest in June and maximum in July, coinciding with the highest mean temperatures and lowest precipitation recorded for the area (Figure 2).

Eight species were collected as adult mosquitoes: *Anopheles (Anopheles) algeriensis* (n = 14), *Aedes (Ochlerotatus) caspius* (n = 152), *Aedes (Ochlerotatus) detritus* s.l. (n = 7), *Coquillettidia richardi* (n = 20), *Culex (Culex) pipiens* (n = 749), *Culex (Culex) theileri* (n = 415), *Culex (Culex) univittatus* (n = 51), and *Culiseta (Allotheobaldia) longiareolata* (n = 24). The most abundant was *C. pipiens* (52%), which peaked in July, as did *A. caspius*, the third most common species (11%). However, *C. theileri* (29%), the second most abundant mosquito, exhibited a slow increase, peaking in August, but maintaining similar levels from July to September. Relative mosquito species densities varied among the seven surveyed lagoons (Figure 3). The dendrogram based on the modified Sorensen coefficient (Southwood, 1978), grouped the surveyed lagoons according to the similarity of their culicid fauna (Figure 4).

IMMATURES

Collection of immature forms in the margins of the seven surveyed lagoons, irrigation ditches and UWTP effluents draining...
to these, in a minimum of 7 and a maximum of 15 biotopes, yielded a total of 85 larvae, with negative collections in the month of July, and a breeding index (R) of 0.2–0.25 in the remaining months (Figure 5). Mean larval density was 0.18 larvae/dipper in June, 0.25 in August, and 0.7 in September. Six species were collected as immatures, *Anopheles* (*Anopheles*) *atroparvus*, *A. caspius*, *Culex* (*Barraudius*) *modestus*, *C. Pipiens*, and *C. theileri*, which varied according to the month (Figure 6), but also according to the nature of the biotope of collection (Figure 7). Physical and chemical parameters of these water collections are presented as their mean values, during the observation period, for each of these lagoons (Table 1).
Table 1 | Physical and chemical parameters* of the seven lagoons surveyed, communication with sea water and effluents of urban wastewater treatment plants, represented as the mean value for the observational period.

| Lagoon               | Sea water | UWTP | pH   | Redox potential (mV) | Conductivity (µS/cm) | TDS (mg/l) | Salinity (ppt) | O₂ mg/l | T °C |
|----------------------|-----------|------|------|----------------------|----------------------|------------|----------------|---------|------|

The higher salinity values recorded are represented in bold.

*Water physical and chemical parameters were measured at about 12:00 a.m.

In brackets are the numbers referring to Figure 1 and the letters referring to Figure 4.

VIRAL SCREENING

A total of 1,249 female mosquitoes were screened for WNV (89% of the total collection), of which 55% (n = 687) were C. pipiens, 31.8% (n = 397) C. theileri, 6.7% (n = 84) A. caspius, 3.8% (n = 47) C. univittatus, 1.6% (n = 20) C. Richardii, and 1.1% (n = 14) A. algeriensis. However, there was no detection of WNV nucleic acid sequences.

DISCUSSION

This survey for mosquitoes along seven lagoons located along the coastal line of the Algarve evidenced a seasonal dynamic of adults, following a typical pattern accompanying the mean temperature, with highest densities in the hottest summer months for temperate climates (Lysyk, 2010). This is not always the case as sometimes, with highest densities in the hottest summer months for temperate regions, where only two, also immature forms, were caught in 1975 (Ramos et al., 1977/1978), in similarly brackish waters as in this study, or not caught at all as adults in later surveys (Ramos et al., 1992; Almeida et al., 2008). C. modestus was not caught as adult probably due to its low abundance, as shown in previous surveys of this very same region, where only two, also immature forms, were caught in 1975 (Ramos et al., 1977/1978), in similarly brackish waters as in this study, or not caught at all as adults in later surveys (Ramos et al., 1992; Almeida et al., 2008). Still, this species is a known vector of WNV in the Mediterranean area (Mouchet et al., 1970).

Immature surveys were mostly negative, with breeding indexes of 0.2–0.25, and, when positive, yielded very few specimens, which may account for the smaller number of species collected in relation to adults. The type of biotopes surveyed, which might not be the preferred ones, may also justify the lesser representation of species as immature stages. The particular biocenose of C. richardi, whose immature stages live attached to stems of aquatic vegetation, requiring special techniques for their collection, is also a likely justification for their absence in immature collections, despite their continued presence as adults in these lagoonal ecosystems (Almeida et al., 2005, 2008). The low level of precipitation, along with increased evaporation, during the summer months, with the consequent decrease in water level and some degree of eutrophication, can be a possible explanation for the low breeding indexes registered. As to the physico-chemical parameters of the water, a pH higher than expected (>8.2) was detected in Salgados and Dunas Douradas lagoons, although this did not reveal to be exclusive of mosquito larval presence, as these were detected closely by Garrão (4, f), though with much lesser abundances. These three lagoons are those closer to UWTPs which can account for that predominance of C. pipiens and relative similarity. Dunas Douradas (4, e) exhibited a quite different culicid fauna, with C. theileri as the overly dominant species, thus placing it far apart from the others. However, the total small sample size may have affected the outcome of this diversity analysis.

Comparing the species collected in different life stages, two were not caught as adults but only as larvae, A. atroparvus and C. modestus, whereas five were not caught as immatures, namely A. algeriensis, A. detritus s.l., C. univittatus, C. Richardii, and C. longiareolata. Furthermore, no relation could be established between species collected in both life stages in each lagoon site. A. atroparvus was not caught as adult, likely due to the collection method used, as this species rarely is attracted to CDC traps, and is mainly found in indoor resting collections (Almeida et al., 2008). C. modestus was not caught as adult probably due to its low abundance, as shown in previous surveys of this very same region, where only two, also immature forms, were caught in 1975 (Ramos et al., 1977/1978), in similarly brackish waters as in this study, or not caught at all as adults in later surveys (Ramos et al., 1992; Almeida et al., 2008).
in Salgados, which had the highest pH registered. The levels of dissolved oxygen measured were always above 5 mg/l, at around noon time, which could indicate much lower levels in the night and dawn as observed in this coastal system (Newton et al., 2010). Furthermore, in the lagoons Garrão and Dunas Douradas, the ichthyofauna was inexcised in 2007 probably due to anoxia in the water and lack of communication with the sea, and high mortality was observed in the Salgados lagoon (CCDR, 2007). Thus, if on one hand, conditions for the presence of mosquito larvae in the waters of these lagoons, do not seem to be very favorable, on the other hand, if colonization by mosquito immatures happened, it could be difficult to be naturally controlled due to the absence of fish, and other, natural predators, such as coleoptera and ephemeropera, which have also very low densities, or are totally absent, in these lagoons (CCDR, 2007).

It is also noteworthy the presence of immature culcids and their species in relation to the nature and site of the biotope. First and foremost, no larvae were found in the margins of any of these lagoons, but only in the ditches discharging to them. In irrigation ditches C. theileri, C. modestus, C. pipiens, and A. atroparvus could be found in progressively lower densities, whereas A. caspius was found just in UWTP effluents. C. pipiens was the only species that was found in both biotopes, however, with much higher densities in the effluents from UWTP, clearly illustrating the capacity of this species to breed in somewhat polluted waters.

Algarve is known to be one of the most touristic places of Portugal, with activities that include bird watching. Some of these lagoons are referenced as bird sanctuaries, with more than a hundred species registered. On the other hand, some of the birds regularly seen in these lagoons, such as Anas platyrhynchos (Mallard) in Salgados, Hirundo rustica (Barn Swallow), and Pandion haliaetus (Osprey) in Garrão, have been found infected with arboviruses such as WNV (CDC, 2011). Some studies also reported the presence of neutralizing antibodies against WNV in birds from Portugal like Buteo buteo (Common Buzzard), Falco tinnunculus (Common Kestrel), and Ciconia ciconia (White Stork) among others (Formosinho et al., 2006), and in other Mediterranean countries like the Turdus merula (blackbirds) and Passer domesticus (house sparrows; Figuerola et al., 2008). Furthermore, some of the bird species found in Portugal like A. platyrhynchos (Mallard), Anas querquedula (Garganey), Ardea purpurea (Purple Heron) are referenced as migratory, thus presenting the risk of pathogen introduction. (Feith, 2007, 2010; Jourdain et al., 2007).

Mosquito species found in this survey, such as A. atroparvus, A. caspius, A. detritus s.l., C. richardi, C. pipiens, C. theileri, C. modestus, and C. univittatus, are known vectors of several arboviruses. Previous human cases of WNV have been putatively acquired in this region (Connell et al., 2004), followed by detection of WNV infected C. pipiens and C. univittatus in the same area (Esteves et al., 2005). A phylogenetic analysis strongly suggested a re-introduction of the virus, since it had first been detected in 1971 (Parreira et al., 2007). In fact, during the last decade WNV has been active in countries lining the Mediterranean (Morocco, Italy, France, Spain, and Greece; Zeller and Schuffenecker, 2004; Rossini et al., 2008; Barzon et al., 2009; Rizzo et al., 2009; Danis et al., 2011a,b). Despite the fact that no mosquito infections were detected in the present study, which may also be due to the small sample size, surveillance should be continued as all previous evidence support the idea that the Algarve, has the conditions for WNV re-mergence, and one of the species previously found infected, C. pipiens, is still the most abundant in several locations and is a known bridge vector, feeding both in birds and humans (Gomes et al., 2009).
