Data Descriptor: High-throughput screening of inorganic compounds for the discovery of novel dielectric and optical materials

Ioannis Petousis1, David Mrdjenovich2, Eric Ballouz3, Miao Liu4, Donald Winston4, Wei Chen4,5, Tanja Graf6, Thomas D. Schladt6, Kristin A. Persson2 & Fritz B. Prinz1,3

Dielectrics are an important class of materials that are ubiquitous in modern electronic applications. Even though their properties are important for the performance of devices, the number of compounds with known dielectric constant is on the order of a few hundred. Here, we use Density Functional Perturbation Theory as a way to screen for the dielectric constant and refractive index of materials in a fast and computationally efficient way. Our results constitute the largest dielectric tensors database to date, containing 1,056 compounds. Details regarding the computational methodology and technical validation are presented along with the format of our publicly available data. In addition, we integrate our dataset with the Materials Project allowing users easy access to material properties. Finally, we explain how our dataset and calculation methodology can be used in the search for novel dielectric compounds.

**Background & Summary**

Dielectric materials are an important component for a plethora of applications in modern electronics, such as Dynamic Random Access Memory (DRAM), flash memory, the Central Processing Unit (CPU), Light Emitting Diodes (LED) and photovoltaics. While high-k dielectrics enable more charge to be stored per unit volume, thus improving performance and driving device size down, low-k materials limit cross-communication, thus enabling devices to be packed closer together. As a result, new dielectric materials with tailored properties are essential for more efficient and better performing electronics as well as miniaturization. Furthermore, with the increasing use of electronics and electric motors in engineering applications, dielectric materials are starting to play a key role in industries such as, automotive, shipping and aerospace. Their specific requirements, however, are quite different to those of consumer electronics, typically requiring longer life as well as greater resistance to mechanical stress and temperature fluctuations.

As a result, there is a need for novel dielectric materials with properties suitable for a range of applications across different industries. However, the number of compounds with known dielectric constant is currently on the order of a few hundred, which drastically limits the options available to the design engineer. The number of inorganic compounds is on the order of 30–50,000 (refs 1–3) hence, there exist tens of thousands of compounds for which the dielectric response remains unknown. Given the sheer size of the chemical compound space, attempting to experimentally search for new dielectrics is not practical considering the time required for synthesis and measurement. On the other hand, Density Functional Perturbation Theory (DFPT) provides a relatively fast and inexpensive method to build a comprehensive dataset from which to derive structure/chemistry—dielectric property correlations and scan for interesting compounds.

The dielectric tensor of a material relates the electric field within the material to that applied externally and is comprised of the electronic as well as ionic contributions. In addition to its importance in defining low- and high-k materials, the dielectric tensor is also useful in the calculation of other material properties (Fig. 1). For example, as demonstrated by Petousis et al.4, it is possible to estimate the refractive index, \( n \), of compounds at optical frequencies with \( \sim 6\% \) deviation from experiments using static DFPT calculations. Furthermore, the ionic and electronic components of the dielectric tensor can be used to predict both the Infrared (IR) and Raman spectra of compounds. Along with the elastic and piezoelectric tensors, the dielectric tensor provides all the information necessary for the solution of the constitutive equations in applications where electric and mechanical stresses are coupled.

Previous studies range from single-compound investigations to high-throughput screening of polymers. More specifically, one high-throughput study7 was related to a specific system \((\text{Zr}_x \text{Si}_{1-x} \text{O}_2)\) and another reported the average dielectric constant for a few tens of inorganic compounds8. There have also been high-throughput studies on dielectrics, specific to organic polymers7. Experimental databases also exist but the total number of compounds listed is on the order of a few hundred.

In this work, we use the methodology established in Petousis et al.4 to generate the largest database of dielectric tensors to date consisting of 1,056 inorganic ordered compounds. Specifically, we report the full dielectric tensor for the total response as well as the electronic and ionic contributions. We also provide an estimate for the refractive index at optical wavelengths and far from resonance. It is worth noting that some of the listed compounds are hypothetical, created in silico by e.g., structure-prediction algorithms10 and have, to our knowledge, not been synthesized yet. As our present work focuses on compound screening, we did not deliberately single out any specific chemical compositions and/or structures for

---

**Figure 1.** Illustration summarizing the quantities calculated in this work and their relation to other, fundamental, material properties.
calculation. Our results are integrated in the Materials Project\textsuperscript{11} which is an open database and aims at employing high-throughput methods to predicting material properties for discovery and design.

**Methods**

**Theory and definitions**

Formally, the dielectric tensor $\varepsilon$ relates the externally applied electric field to the field within the material and can be defined as:

\[
E_i = \sum_j \varepsilon_{ij}^{-1} E_{0j}
\]

(1)

where $E$ is the electric field inside the material and $E_{0}$ is the externally applied electric field. The indices $i, j$ refer to the direction in space and take the values: $\{1, 2, 3\}$. The dielectric tensor can be split in the ionic ($\varepsilon_0$) and electronic ($\varepsilon_\infty$) contributions:

\[
\varepsilon_{ij} = \varepsilon_{ij}^0 + \varepsilon_{ij}^\infty
\]

(2)

Here, we consider only the response of non-zero band gap materials to time-invariant fields. In the hypothetical case that a material does not respond at all to the external field, $\varepsilon_{ij}^\infty$ would be equal to the identity tensor and $\varepsilon_{ij}^0$ would be zero. In fact, materials with zero ionic contribution do exist. In general, for $\varepsilon_{ij}^0$ to be non-zero, compounds need to have at least 2 atoms per primitive cell, each having a different atomic charge.

The dielectric tensor is symmetric and respects all the symmetry operations of the corresponding point group. This limits the number of independent elements in the tensor to a minimum of 1 and a maximum of 6 depending on the crystal symmetry (Table 1).

The dielectric response calculated herein corresponds to that of a single crystal. In polycrystalline samples, grains are oriented randomly and hence, the actual response will be different. Nevertheless, the upper and lower bounds of the polycrystalline dielectric constant have proven to be\textsuperscript{12}:

\[
\frac{3}{1/\lambda_1 + 1/\lambda_2 + 1/\lambda_3} < \varepsilon_{\text{poly}} < \frac{\lambda_1 + \lambda_2 + \lambda_3}{3}
\]

(3)

where $\lambda_1, \lambda_2, \lambda_3$ are the eigenvalues of the single crystal dielectric tensor. Of course, the above inequality takes into account only the different orientation of the grains and ignores effects due to e.g., impurities or other kinds of defects. For the sake of simplicity, here we estimate the polycrystalline dielectric constant using the simple average, i.e., we define:

\[
\varepsilon_{\text{poly}} = \frac{\lambda_1 + \lambda_2 + \lambda_3}{3}
\]

(4)

Generally, the dielectric response varies with the frequency of the applied external field however here, we consider the static response (i.e., the response at constant electric fields or the long wavelength limit). Since the ionic contribution vanishes at high frequencies, our results can be used to obtain an estimate of the refractive index, $n$, at optical frequencies and far from resonance effects using the well known formula\textsuperscript{a}:

\[
n = \sqrt{\varepsilon_{\text{poly}}^\infty}
\]

(5)

where $\varepsilon_{\text{poly}}^\infty$ is the average of the eigenvalues of the electronic contribution to the dielectric tensor. It should be noted that equation (5) assumes the material is non-magnetic.

| Crystal System | Point Groups | Dielectric Tensor | No. of independent elements |
|----------------|--------------|-------------------|-----------------------------|
| Cubic          | 23, m\overline{3}, 432 \text{ mm}, m\overline{5m} | $\begin{pmatrix} \varepsilon_{11} & 0 & 0 \\ 0 & \varepsilon_{22} & 0 \\ 0 & 0 & \varepsilon_{33} \end{pmatrix}$ | 1 |

| Orthorhombic   | 222, mm\overline{2} \text{ mmm} | $\begin{pmatrix} \varepsilon_{11} & 0 & 0 \\ 0 & \varepsilon_{22} & 0 \\ 0 & 0 & \varepsilon_{33} \end{pmatrix}$ | 3 |
| Monoclinic     | 2, 2/m | $\begin{pmatrix} \varepsilon_{11} & 0 & 0 \\ 0 & \varepsilon_{22} & 0 \\ \varepsilon_{13} & 0 & \varepsilon_{33} \end{pmatrix}$ | 4 |
| Triclinic      | 1, \text{ 1} | $\begin{pmatrix} \varepsilon_{11} & \varepsilon_{12} & \varepsilon_{13} \\ \varepsilon_{12} & \varepsilon_{22} & \varepsilon_{23} \\ \varepsilon_{13} & \varepsilon_{23} & \varepsilon_{33} \end{pmatrix}$ | 6 |

Table 1. Dielectric tensors shape for different crystal symmetries.
Computational workflow

The workflow for calculating the dielectric constant is similar to the one used and extensively benchmarked against experimental data, by Petousis et al.\textsuperscript{4} (Fig. 2). All structures were downloaded from the Materials Project database\textsuperscript{11,13,14}. To ensure a good starting set of materials (e.g., well-relaxed, stable structures), we apply the following 3 selection criteria: 1) the DFT band gap should be greater than 0.1 eV, 2) the hull energy in the phase diagram should be less than 0.02 eV and 3) the interatomic forces of the starting structure should be less than 0.05 eV/Å. It should be noted here that since we are using perturbation theory, our structure should ideally be as close to the ground state as possible. However, in practice\textsuperscript{4} we found that a threshold value of 0.05 eV/Å for the interatomic forces leads to acceptable errors for our screening methodology. For computational efficiency we, at this point, limit the set of calculated compounds to those with \( \leq 20 \) atoms per supercell. After the DFPT calculation, the validity of the calculation is checked by ensuring the energy of the acoustic phonon modes at the Gamma point is less than 1 meV and that the dielectric tensor respects the point group symmetry operations with an error less or equal to 10\% (relative) or 2 (absolute). The latter was in practice implemented by applying the symmetry operation to the tensor and ensuring that no tensor element changed by more than 10\% or 2 with respect to the mean value of the original tensor element and of the tensor element after the symmetry operation was applied.\textsuperscript{4} Furthermore, if we find imaginary optical phonon modes at the Gamma point, we tag those compounds as potentially ferroelectric.

For the DFPT calculations we used the Vienna Ab-Initio Simulation Package\textsuperscript{15–18} (VASP version 5.3.4) combined with the Generalized Gradient Approximation GGA/PBE\textsuperscript{19,20}+U\textsuperscript{21,22} exchange-correlation functional and Projector Augmented Wave pseudopotentials\textsuperscript{23,24}. The U values are energy corrections that address the spurious self-interaction energy introduced by GGA. Here, we used U values for \( d \) orbitals only that were fitted to experimental binary formation enthalpies using Wang et al.\textsuperscript{25} method. The full list of U values used, can be found in ref. 22. The k-point density was set at 3,000 per reciprocal atom and the plane wave energy cut-off at 600 eV (ref. 4). For detailed information on the calculation of the dielectric tensor within the DFPT framework we refer to Baroni et al.\textsuperscript{26,27} and Gonze & Lee\textsuperscript{28}.

Code availability

The DFPT calculations in this work were performed using the proprietary code VASP. The pre-and post-processing of the simulations was achieved using pymatgen\textsuperscript{13} and FireWorks\textsuperscript{29}. Pymatgen\textsuperscript{13} is open-source software under the Massachusetts Institute of Technology (MIT) license. The workflow in Fig. 2 was implemented in FireWorks\textsuperscript{29} which is publicly available under a modified GNU General Public License.
Data Records
The calculated dielectric tensors and refractive indices are available on the Materials Project\textsuperscript{13} website (www.materialsproject.org) and can be downloaded using the Materials Project API\textsuperscript{14}. On the website, it is also possible to query for compounds with a certain dielectric response and refractive index by applying the appropriate filters on the search engine. Additionally, the Materials Project website provides information about the simulation parameters, crystal structure and other properties. The results are also available in the form of a JSON file that can be downloaded directly from the Dryad repository (Data Citation 1).

File format
The data for each of the calculated compounds are stored in a list and are provided as a JSON file. For each compound, there are key values, such as ‘\(\varepsilon_{\text{electronic}}\)’ and ‘\(\varepsilon_{\text{ionic}}\)’, that point to the appropriate property (Table 2). The key ‘meta’ contains all the appropriate metadata and has its own keys which are one level down in hierarchy. The metadata keys are presented in Table 3.

Graphical representation of results
In Fig. 3, we show a violin plot of the electronic and ionic contribution components of the dielectric constant for all calculated compounds, grouped according to the crystal system. Firstly, the plot shows that, as discussed above, the ionic contribution can be zero in contrast to its electronic counterpart. Furthermore, we observe the distribution of \(\varepsilon_{\text{pol}}\) to be similar and relatively larger for cubic and orthorhombic crystals. However, monoclinic and triclinic crystals show lower values for the ionic component. This could be due to the lower level of symmetry and hence, the lack of phonon contributions to \(\varepsilon_{\text{pol}}\).

In Fig. 4 we superimposed the lines \(\varepsilon_{\text{pol}} \cdot E_g = c\) and \(\sqrt{\varepsilon_{\text{pol}} \cdot E_g} = c\) (where \(E_g\) represents the band gap of the material and \(c\) is a constant). These quantities are proxies to the figures of merit for current leakage\textsuperscript{8} and energy storage\textsuperscript{9} of a capacitor respectively. Since for high-k dielectrics, both high \(\varepsilon_{\text{pol}}\) and \(\sqrt{\varepsilon_{\text{pol}} \cdot E_g}\) are desired in order to limit leakage and maximize energy storage in applications, we identified the best performing compounds out of the ones calculated and highlighted them in Fig. 4. Thus, the design of new and better performing dielectric materials effectively becomes a battle against the inverse relationship between \(\varepsilon_{\text{pol}}\) and \(E_g\).

Another point worth noting is that although polymers follow the general trend of inorganic compounds, they do not seem to have the high dielectric constant outliers that inorganics exhibit. We believe this is due to the fact that inorganics, being structurally more ordered than polymers, can benefit from a significant contribution to the dielectric constant from the optical phonon modes.

| Key                  | Datatype | Description                                                                 |

Table 2. Description of metadata keys.
The discussion above provides insight on the search for new high-k dielectrics that break the inverse relationship apparent in both Figs 4 and 5. Thus, we suggest that materials with the following characteristics might have superior dielectric properties:

1. Flat conduction and valences band (d and f orbitals might help achieve this).
2. Crystal symmetries that have been known to have significant ionic contributions to the dielectric constant (e.g., Fm\overline{3}m, R\overline{3}c).

However, we emphasize that the ionic components tend to zero at high field frequencies and hence, the effective dielectric constant might be significantly different at THz or GHz applications.

**Low-k dielectrics**

Since the band gap can be thought as a proxy to how insulating a material is, good low-k dielectrics will also have large $E_g$. However, in this case the advantage is that high band gap materials naturally have a low dielectric constant. Additionally, suppressing the ionic contributions might be beneficial. For this, the selection of low symmetry structures and elements with small difference in electronegativity may be helpful.

**Figure 3. The polycrystalline estimate of the dielectric constant for the different crystal systems.** The violin outlines are the Gaussian kernel density estimates of the data points that appear in the middle and are calculated using $f(x) = \frac{1}{nh} \sum_{i=1}^{n} K\left(\frac{x-x_i}{h}\right)$ where K is the Gaussian kernel and $h$ is a smoothing parameter (estimated here using Scott’s normal reference rule). The left (blue) refers to the electronic component while the right (yellow), to the ionic. The total number of compounds in each crystal system was: 236, 132, 254, 183, 166, 11 and 74 (for cubic, hexagonal, trigonal, tetragonal, orthogonal, monoclinic and triclinic respectively).
Technical Validation

The high-throughput calculation methodology and workflow used in the present study were validated in Petousis et al.\textsuperscript{4}. Specifically, the eigenvalues of the total dielectric tensor were compared to experimental values for a set of representative compounds. This set was made up of 88 compounds consisting of 42 different elements and belonging to 14 different point groups. In cases where larger than average deviations from experiments existed, the quality of the results was ensured by confirming agreement with other state-of-the-art and compound-bespoke DFPT calculations reported in the literature. In the same reference, the method for calculating the refractive index at optical frequencies and far from resonance was also validated by comparing against experimental data found in the literature for a subset of 87 compounds.

Figure 4. The polycrystalline estimate of the dielectric constant ($\varepsilon_{\text{poly}}$). The x-axis represents the DFT-GGA+U band gap values ($E_g$) obtained from the Materials Project website. There is a total of 1,056 data points for inorganic compounds. The red data points refer to values for polymers calculated by Huan et al.\textsuperscript{31} Red and green lines represent the figures of merit ($\varepsilon_{\text{poly}}$, $E_g$) and ($\varepsilon_{\text{poly}}$, $E_g^{1/2}$) respectively. The formulas of promising compounds with $\varepsilon_{\text{poly}}$, $E_g > 16$ and $\varepsilon_{\text{poly}}^{1/2}$, $E_g > 160$, are shown on the graph. HfO$_2$, SiO$_2$ and polyethylene are also shown for information.

Figure 5. The polycrystalline estimate of the refractive index versus band gap for the different crystal systems. There appears to be no trend between the refractive index/band gap inverse relationship and the crystal system the material belongs to.
As described in more detail in the Methods section, each calculation was tested for validity by checking the acoustic phonons at the Gamma point and the symmetry of the dielectric tensor. Furthermore, when the information was available, our results were checked against other experimental values reported in the literature. The comparison is presented in Fig. 7 and Table 4. We observe that in most cases materials deviate less than +/-25% from experiments. There are many factors that are not included in the DFPT model and contribute to this deviation e.g., (1) temperature, (2) pressure, (3) grain boundaries, (4) defects, (5) surface effects, (6) phonon anharmonicity. It should be noted that experimental values also vary between different studies. A detailed analysis of the reasons for deviation from experiments can be found in Petousis et al.\textsuperscript{4}. The Mean Absolute Deviation (MAD) and Mean Absolute Relative Deviation (MARD) were extracted as 2.0 and 19.0% respectively, which we consider acceptable for a screening methodology. Once promising candidate materials are identified, further calculations and analyses can be performed to obtain a better estimate.

Furthermore, Fig. 8 shows the effect of structural relaxation and remnant interatomic forces on the dielectric constant. In particular, we plot the dielectric constant for a subset of 90 compounds where on the x-axis, interatomic forces are less than 0.05 eV/Å but higher than 0.01 eV/Å and on the y-axis they are less 0.01 eV/Å for the same compounds. Figure 8 shows that although the deviation between the two cases, is on average relatively small (0.22 absolute and 2.23% relative deviations), there are cases for which this deviation can be significant (e.g., 1.92 and 16.65%).

**Figure 6.** The density of states for PtS\textsubscript{2} and GaAgO\textsubscript{2}. PtS\textsubscript{2} has a higher electronic dielectric constant than GaAgO\textsubscript{2}, even though its band gap is larger.

**Figure 7.** Comparison of calculated values ($\varepsilon_{\text{poly}}$) versus experimental values in the literature. The lines indicate the relative deviation of the calculated values with respect to experiments. The Mean Absolute Deviation (MAD) and Mean Absolute Relative Deviation (MARD) were extracted as 2.0 and 19.0% respectively. Data points are listed in Table 4.
Usage Notes
We present a database of calculated dielectric constant and refractive index for 1,056 compounds. Our work should be of interest to researchers and engineers from a number of different fields, for example,

![Figure 8. Plot showing the effect of remnant interatomic forces.](image)

Supervising and planning the work and its integration with the Materials Project effort. F.B.P. was planning the work. T.D.S. was involved in supervising and planning the work. K.A.P. was involved in website. W.C. was involved in supervising and planning the work. T.G. was involved in supervising and planning the work.

Author Contributions

This work was supported financially by the Volkswagen Group. K.A.P., W.C., D.W., M.L. and D.M. gratefully acknowledge support from the Materials Project Center, under the Department of Energy, Basic Energy Sciences Grant No EDCBEE. The calculations were performed using the computational resources of the National Energy Research Scientific Computing Center, which is supported under the Office of Science of the U.S. Department of Energy under Contract No DE-AC02-05CH11231.

Acknowledgements

I.P. performed the dielectric constant and refractive index calculations, developed the algorithm and the code, performed the data verification and analysis and wrote the paper. D.M. obtained experimental data from the literature. E.B. obtained experimental data from the literature. M.L. wrote the code to upload the raw data on the Materials Project website. D.W. developed the web interface on the Materials Project website. W.C. was involved in supervising and planning the work. T.G. was involved in supervising and planning the work. T.D.S. was involved in supervising and planning the work. K.A.P. was involved in supervising and planning the work and its integration with the Materials Project effort. F.B.P. was involved in supervising and planning the work.
