ABSTRACT

Over the last decade, X-ray observations unveiled the existence of several classes of isolated neutron stars (INSs) which are radio-quiet or exhibit radio emission with properties much at variance with those of ordinary radio pulsars. The identification of new sources is crucial in order to understand the relations among the different classes and to compare observational constraints with theoretical expectations. A recent analysis of the 2XMMp catalogue provided less than 30 new thermally emitting INS candidates. Among these, the source 2XMM J104608.7-594306 appears particularly interesting because of the softness of its X-ray spectrum, \( kT \approx 117 \pm 14 \text{ eV} \) and \( N_H = (3.5 \pm 1.1) \times 10^{21} \text{ cm}^{-2} \) (3\,\sigma), and of the present upper limits in the optical, \( m_V \gtrsim 26 \), \( m_g \gtrsim 25 \) and \( m_R \gtrsim 25 \) (98.76\% confidence level), which imply a logarithmic X-ray-to-optical flux ratio \( \log(F_X/F_\text{opt}) \gtrsim 3.1 \), corrected for absorption. We present the X-ray and optical properties of 2XMM J104608.7-594306 and discuss its nature in the light of two possible scenarios invoked to explain the X-ray thermal emission from INSs: the release of residual heat in a cooling neutron star, as in the seven radio-quiet \textit{ROSAT}-discovered INSs, and accretion from the interstellar medium. We find that the present observational picture of 2XMM J104608.7-594306 is consistent with a distant cooling INS with properties in agreement with the most up-to-date expectations of population synthesis models: it is fainter, hotter and more absorbed than the seven \textit{ROSAT} sources and possibly located in the Carina Nebula, a region likely to harbour unidentified cooling neutron stars. The accretion scenario, although not entirely ruled out by observations, would require a very slow (\( \sim 10 \text{ km s}^{-1} \)) INS accreting at the Bondi-Hoyle rate.

Key words. stars: neutron – X-rays: individuals: 2XMM J104608.7-594306 – Catalogs

1. Introduction

A major outcome of the \textit{ROSAT} mission has been the discovery of a group of radio-quiet isolated neutron stars (INSs) with properties clearly at variance from the bulk of the population of rotation-powered pulsars. At present, the group comprises seven objects (whence the nickname “Magnificent Seven”, or M7) sharing similar properties, which include purely thermal X-ray spectra with very soft temperatures (\( kT \sim 40-100 \text{ eV} \)) and low absorption column densities (\( N_H \sim \text{few } 10^{20} \text{ cm}^{-2} \)), long spin periods (\( P \sim 3-10 \text{ s} \)), intense magnetic fields (\( B \sim 10^{13-10^{14}} \text{ G} \)), very faint optical counterparts (\( m_B \gtrsim 25 \text{ when detected} \)), implying X-ray-to-optical flux ratios \( F_X/F_\text{opt} \gtrsim 10^3 \) and no associations with supernova remnants or stellar companions (see e.g. \textit{Haber} 2007, for a recent review).

For some time, following the pioneering work by \textit{Ostriker et al.}(1970) and \textit{Shvartsman}(1971), it was thought that these sources might belong to the long sought population of old INSs powered by accretion of the interstellar medium (ISM), which was expected to be detected by \textit{ROSAT} (see \textit{Treves et al.} 2000, for a review). However, the measurement of large proper motions (e.g. \textit{Motch et al.} 2007, 2008, and references therein) strongly supports the idea that the M7 represent a local population (\( d \lesssim 500 \text{ pc} \)), \textit{Posselt et al.} 2003, \textit{van Kerkwijk & Kaplan} 2007) of middle-aged neutron stars (\( \sim 10^5-10^6 \text{ yr} \)), which give off thermal radiation as they cool down. The similar spin periods and their position on the \( P-\dot{P} \) diagram raised the possibility that they could be related to other populations of INSs – like magnetars, high magnetic field radio pulsars (HBPSRs) and rotating radio transients (RRATs; \textit{McLaughlin} et al. 2006) – which is an intriguing and still debated issue (e.g. \textit{Popov} et al. 2006, \textit{Kaplan} 2008, \textit{Keane} & \textit{Kramer} 2008).

Considering that within 1 kpc the M7 appear in comparable numbers as young (\( \lesssim \text{few } 10^5 \text{ yr} \)) radio and \( \gamma \)-ray pulsars (\textit{Popov} et al. 2003), they may represent the only identified members of a large, yet undetected, elusive population of radio-quiet and thermally emitting INSs. The discovery of new candidates is then mandatory in order to make any progress towards an understanding of their properties as a population and of their relations with other classes of Galactic INSs.

Despite the relatively small field of view and low sky coverage of the \textit{XMM-Newton} Observatory\textsuperscript{5}, its large effective area and good positional accuracy at soft X-ray energies make it ideal

\hspace{1cm}\footnote{1 In a near future, \textit{eROSITA} will become an excellent tool to search for INSs (http://www.mpe.mpg.de/projects.html\#erosita).}
2.1. Observations and data reduction

Table 1. Description of the set of XMM-Newton and Chandra observations that serendipitously detected source XMM J1046. The exposure times ($t_{\text{exp}}$), filtered for background flares, and the effective exposures ($t_{\text{eff}}$) on XMM J1046, accounting for vignetting, are reported; $\theta$ is the source off-axis angle. Net source photons and the on-axis count rates are in the 0.15–3 keV (XMM-Newton) and 0.5–3 keV (Chandra) energy bands.

To look for faint INS candidates. Recently, Pires & Motch (2008) reported the preliminary results of a programme aimed at identifying new thermally emitting INSs in the 2XMMp catalogue. This version of the catalogue, released on July 2006, contains more than 12 thousand sources, covering a total sky area of ∼285 deg$^2$. Out of the considered ∼7.2x10$^4$ EPIC pn sources with count rates above 0.01 s$^{-1}$, less than 30 good candidates met all the selection criteria – i.e. well detected point-like sources showing soft thermal spectrum ($kT \lesssim 200$ eV and $N_H = 10^{19} - 10^{22}$ cm$^{-2}$), with no optical candidates and no identifications in over 170 astronomical catalogues. The brightest and most promising INS candidate is source 2XMM J104608.7-594306 (hereafter XMM J1046). In this work we discuss the properties of XMM J1046 in connection with the two main options concerning its nature, a cooling or an accreting INS. The description of the selection procedure and the results of follow-up optical observations on a sample of the X-ray brightest INS candidates will be presented elsewhere (Pires et al., in preparation).

2. XMM J1046 in X-rays and the optical

2.1. Observations and data reduction

Thanks to the fact that source XMM J1046 is at an angular distance of only ∼8.5 arcmin from the well studied binary system Eta Carinae, it was serendipitously observed by the EPIC pn and MOS detectors on board XMM-Newton on many different occasions. As part of an observational campaign to study the star-forming region of the Carina Nebula, XMM J1046 was also serendipitously observed once in a recent Chandra observation (September 2008). Although this X-ray mission has observed Eta Carinae many times, XMM J1046 was not detected before given the smaller field of view of the ACIS instruments relative to the EPIC cameras.

We analysed 16 XMM-Newton archival observations, spanning from July 2000 to February 2006, in which XMM J1046 was visible. The event files were processed applying standard procedures with SAS 7.1. The MOS and pn observations were reduced using emchain and epchain, respectively, applying default corrections. The event lists were filtered for intervals of high background activity as well as to retain the pre-defined patterns corresponding to single, double, triple and quadruple pixel events, for the MOS observations, and single and double pixel events, for the pn observations, as these have the best energy calibration. Source and background events were extracted using circular regions of radii ∼25 arcsec (centered on the position of the X-ray source) and ∼50 arcsec, respectively. Background regions were defined on an area free of sources in the same CCD and roughly at the same distance from the readout node as the source region. We restricted our analysis to the 0.15–3 keV energy range. Whenever possible for a given observation, data from all EPIC cameras were analysed simultaneously to better constrain the spectral parameters.

3 http://xmm.esac.esa.int/sas
The Chandra observation was analysed using CIAO 4.0.1 and CALDB 3.4.4. We processed the event files with the task `acis_process_events`, also applying default corrections. Since the observation was taken in VFAINT mode, we cleaned the ACIS background while processing the event file. We checked for the presence of known processing offsets using the aspect calculator tool available on the CIAO web pages. Finally, we selected events corresponding to grades 0, 2, 3, 4 and 6 (in ASCA terminology) and applied the good time intervals, also filtering for periods of background flares. For the spectral analysis, we used the 0.5–3 keV energy band due to the molecular contamination that is degrading the quantum efficiency of the ACIS front-illuminated chips, at energies below 0.5 keV. Source and background regions were extracted applying similar criteria as for XMM-Newton data. In Table 2, we list, for every observation, the effective exposure times, off-axis angles, the number of extracted source photons for the spectral analysis and the source count rate, corrected for vignetting, in the given energy bands.

### 2.2. Spectral analysis

EPIC and Chandra images do not reveal any particular background enhancement close to the X-ray source. However, the Chandra data, which benefit from a lower instrumental background, do show some weak diffuse extended emission (a filamentary structure roughly consistent with some large-scale nebulosity seen in the optical). The brightest part is located 5 to 7 arcmin south-east of the X-ray source. This filament is not detected on the XMM-Newton images, although it is marginally in the field of view of the EPIC cameras. None of the background regions used in the spectral analysis overlaps with this diffuse X-ray emission. Therefore, it is expected that the noise for the EPIC data is dominated by the (position independent) instrumental background. The noticeable vignetting and spreading of the PSF prevailing at the large off-axis angles where the source stands in many XMM-Newton observations both contribute to the difficulty in measuring the spectrum of XMM J1046 in these cases.

Spectra were binned requiring a different minimum number of counts per energy bin, depending on the total number of source counts. Spectra extracted from the shortest exposures have at least 5 counts per bin. Using XSPEC 12.6, we tested different models (blackbody, power law, bremsstrahlung, Raymond-Smith, . . .), allowing the fit parameters to vary freely. Due to the low number of counts, we applied the maximum likelihood C statistic (Cash 1979) in order to derive the best fit parameters and their uncertainties. The quality of each fit (“goodness”) is estimated by means of Monte Carlo simulated spectra, drawn from the best fit model, and the distribution of corresponding C fits statistics. If most (>50%) of the simulated spectra has a smaller fit statistic than the current model, then it is unlikely that the observed data were drawn from the model.

The spectrum of XMM J1046 is always best fitted by a single absorbed soft blackbody; other models (in particular, power law, optically thin thermal plasmas and magnetized neutron star atmospheres) invariably result in worse fits and there is no evidence for an additional (hard) component. In general, the X-ray emission of radio pulsars results from the sum of thermal and non-thermal components (see e.g. Kaspi et al. 2004 for a review). A power law component usually dominates the X-ray emission of young pulsars (age ≤ 10^5 yr) while old pulsars (age ≥ few Myr) exhibit a weak thermal component, probably originating from small heated polar caps, in addition to a dominating power law. On the other hand, the X-ray emission of the middle-aged pulsars (age ~ few 10^5 yr) known as “Three Musketeers” is clearly dominated by soft blackbody components superposed on a high energy tail with photon indexes 1.7–2.1 (e.g. De Luca et al. 2005). The addition of a power law component with similar photon indexes to the blackbody model does not improve the fit of XMM J1046. Any power law component contributes at most 4% (3σ confidence level, 0.5–10 keV range) to the source luminosity. Therefore, a power law flux as low, relative to the thermal component, as that of the Three Musketeers (0.3–1.7%) would not be detectable in XMM J1046 with the available data and can not be presently excluded. However, an X-

ray spectrum dominated by a non-thermal component is clearly ruled out.

The M7 show rather stable spectral and timing properties. In particular, the X-ray brightest source RX J1856.5-3754 shows very constant flux and spectral properties over several years. Its X-ray spectrum is remarkably well reproduced by a blackbody with no significant deviations (e.g. Burwitz et al. 2003). On the other hand, the second brightest source RX J0720.4-3125 is the only one among the M7 that has been shown to undergo long-term variations in its spectral parameters, at more or less constant flux. This behaviour is either possibly cyclic and related to the star precession (Haberl et al. 2006; Hohle et al. 2008, and references therein) or impulsive, being interpreted as a sudden change on the neutron star surface accompanied with a simultaneous torque, caused by an accretion or glitch episode (van Kerkwijk et al. 2007).

Considering the 16 XMM-Newton observations, single absorbed blackbodies have temperatures and column densities ranging from $76^{+28}_{-26}$ to $160^{+31}_{-23}$ eV and from $(1.4^{+0.9}_{-0.8}) \times 10^{21}$ to $(8.5^{+6.6}_{-2.8}) \times 10^{21}$ cm$^{-2}$; errors are 1σ. In some cases, the small number of counts prevents a well constrained fit. In order to check the significance of the variations of the spectral parameters of XMM J1046, we performed a χ² test on the 16 XMM-Newton observations, assuming that they do not change in time and have values equal to their respective weighted means $kT = 113^{+11}_{-10}$ eV and $N_H = (3.6^{+0.9}_{-0.8}) \times 10^{21}$ cm$^{-2}$ (hereafter, reported errors on the weighted means are 3σ, unless otherwise noted). We found that $kT$ and $N_H$ are consistent with being the same in all observations at an acceptable but low confidence level for the temperature ($χ^2 ∼ 26$ and $χ^2 ∼ 19$ for 15 degrees of freedom, respectively; the probabilities of getting a larger $χ^2$ are ∼ 4% and ∼ 19%). However, we note that among the data sets with the largest values of $χ^2$ there are some observations for which the source elongated point spread function (PSF) overlaps the CCD gaps of the EPIC instruments. The correction for the missing part of the energy-dependent PSF might not be well calibrated, in particular at large off-angles (XMM J1046 is located at ∼ 9 arcmin, on average, but its off-axis angle can be as large as ∼ 15 arcmin, see Table 1). This would require the inclusion of an additional systematic error which would have the effect of lowering the $χ^2$ values. On the other hand, if we only consider the 10 observations for which the source is not located close to a gap, we find that the temperature and column density are steady over the six-year time interval at rather high confidence levels: $kT = 117^{+14}_{-0.7}$ eV (23%) and $N_H = (3.5^{+0.1}_{-0.1}) \times 10^{21}$ cm$^{-2}$ (44%), see Table 2.

Alternatively, if the column density is held constant to the mean value $N_H = 3.5 \times 10^{21}$ cm$^{-2}$, the computed range in $kT$ is narrower, 111–132 eV, and the parameters are better constrained (1σ errors correspond to ∼ 5% of the best values against ∼ 20% when $N_H$ is free to vary, see Table 2 for the individual fits). In this case, the variations in $kT$ are statistically significant (99.26%). We note, however, that the sample of analysed observations is highly heterogeneous and thus subject to systematic uncertainties. In particular, the different observing conditions – distance to the optical axis, observing modes and cameras – as well as calibration uncertainties at energies below 0.5 keV especially for the MOS cameras, do not allow one to draw definite conclusions on the source intrinsic spectral variability. Hereafter, we adopt the weighted mean blackbody temperature and column density of the 10 best XMM-Newton observations for the purpose of further discussion on the source properties. In Fig. 1 the individual best fits are plotted together with the $N_H \times kT$ contours obtained fitting all data with one single blackbody model.

A slightly more absorbed blackbody fit is found for the Chandra observation (Table 2). We note, however, that the response of the front-illuminated ACIS chips is not best suited to derive the spectral parameters of a source as soft as XMM J1046. This, and the fact that only photons with energies above 0.5 keV were considered, act together to cast some doubts on the column density derived in the blackbody fit. In Fig. 2 we show the spectral fits of the two data sets with the best signal-to-noise ratio among the analysed data.

The weighted mean of the 0.15–3 keV observed flux is $f_X = (9.7 \pm 0.5) \times 10^{-14}$ erg s$^{-1}$ cm$^{-2}$, considering the 16 XMM-Newton observations; the computed range is $(7.7 \pm 0.7) \times 10^{-14}$ to $(12.9^{+1.7}_{-1.6}) \times 10^{-14}$ erg s$^{-1}$ cm$^{-2}$ (1σ). Although a constant flux is not statistically acceptable ($χ^2 = 43$ for 15 degrees of freedom), a long term variability is excluded once the fluxes in the EPIC cameras are considered separately: the averaged flux in the pn camera is systematically fainter than that measured in the MOS cameras but both are consistent with a constant flux (at confidence levels of ∼ 19% and ∼ 92%, respectively). The same ∼ 13–20% discrepancy between the two instruments is seen in the three observations where both cameras were simultaneously

---

8 The errors on $N_H$ reported in Pires & Motch (2008, Table 2) should be multiplied by a factor 10.
9 Observations flagged with “no” in Table 1.

Fig. 1. Contour plot corresponding to the overall X-ray fit of source XMM J1046, using the 10 best XMM-Newton observations ($kT = 122^{+8}_{-10}$ eV and $N_H = 3.6^{+0.6}_{-0.7} \times 10^{21}$ cm$^{-2}$; errors are 3σ). The $kT \times N_H$ parameter space is shown for 1σ, 2σ and 3σ confidence levels. The individual best fits of Table 2 are shown as crosses with 1σ error bars.

http://xmm2.esac.esa.int/docs/documents/CAL-TN-0018.pdf
on. According to recent cross-calibration studies\(^\text{[1]}\), the MOS cameras register 7–9% higher flux than pn below 4.5 keV\(^\text{[2]}\) and this excess increases with off-axis angle. The larger discrepancy can thus be explained by the large off-axis angle of XMM J1046 in the set of analysed observations. The probabilities that temperature and column density are constant also increase when the cameras are considered individually (a consequence of the larger errors), but there is no systematic relation as for the flux (i.e. the weighted mean values are roughly the same).

Once again, accounting only for the set of 10 observations not close to a gap, the overall picture further argues against significant flux variations: the MOS and pn fluxes can be considered to be constant either when the cameras are analysed together or separately (Fig. 3). The weighted means and respective confidence levels for the two cameras are \(f_{X,\text{pn}} = (9.4 \pm 1.1) \times 10^{-14} \text{erg s}^{-1} \text{cm}^{-2}\) (44%) and \(f_{X,\text{MOS}} = (1.07 \pm 0.08) \times 10^{-13} \text{erg s}^{-1} \text{cm}^{-2}\) (78%). Despite of the discrepancy between the two instruments, the fluxes are compatible within errors. We adopt here the mean value of the flux as measured by the two cameras, which is also consistent with the value inferred when the cameras are analysed together \(f_X = (1.03 \pm 0.06) \times 10^{-13} \text{erg s}^{-1} \text{cm}^{-2}\). A direct comparison of the source count rate, corrected for vignetting, for the MOS cameras, is also shown in Fig. 3.

\[\text{Fig. 2. X-ray spectra and best fits of source XMM J1046 as observed with XMM-Newton (left, OBSID 311990101, pn and MOS2 cameras; the two lower data points consist of two subsequent MOS2 exposures) and Chandra (right, ACIS-I). The contour plots in the insets show the } kT - N_{\text{H}} \text{ parameter space for } 1\sigma, 2\sigma \text{ and } 3\sigma \text{ confidence levels.}\]

2.3. Timing analysis

One of the most intriguing and discernible features of the M7 is that, when compared to radio pulsars, the neutron star spin periods are longer and distributed in a much narrower range. Six of the sources show sinusoidal X-ray pulsations with pulsed fractions between \(1\%\) and \(18\%\). The detection of pulsations in the X-ray emission of source XMM J1046 would represent further evidence to unveil its nature. However, despite of the large number of archival observations that detected the source, only one (OBSID 311990101, pn) is really suitable to conduct timing analysis – the others being either too short and having few source counts or, for the MOS observations, taken in full frame mode which has a too poor frame resolution (2.6 s) for timing purposes. Similarly, the Chandra data was carried out with a 3.4 s time resolution imaging configuration.

With the aim to search for pulsations, we converted the photon arrival times of the pn observation from the local satellite to the solar system barycentric frame using the SAS task barycen. Source photons were extracted in a smaller elliptical region (relative to the extracted region for the spectral analysis) in order to avoid background events. For the same reason and, since XMM J1046 does not show counts above \(1.5 \text{ keV}\), we only considered the 0.15–2 keV energy range. We next searched for pulsations using a \(Z^2_r\) (Rayleigh) test\(^\text{[3]}\) by Buccheri et al. 1983). No pulsations are found to a non-constraining 30% upper limit (3\(\sigma\)), in the 0.073–100 s period range; the dimness of the source would require a longer exposure in order to significantly constrain the upper limit on pulsations.

2.4. Optical follow-up

Follow-up optical observations performed in the B and R bands at the ESO Very Large Telescope (VLT) in February 2007 revealed no counterpart within \(\sim 4.3 \text{ arcsec} (\gtrsim 5\sigma)\) from the position of XMM J1046, \(\alpha = 10:46:08.72\), \(\delta = -59:43:06.4\), as derived running the SAS task emidetect on the best XMM-Newton observation 311990101. The 90% confidence level error circle on the position, \(r_{90} = 1.33 \text{ arcsec}\), is given by \(2.15 \sqrt{\sigma^2 + \sigma_{\text{sys}}^2}\) where \(\sigma\) is the nominal error as given by emidetect and \(\sigma_{\text{sys}}\) is the systematic error on the detection position as provided by the 2XMMp catalogue, based on reliable cross-correlation with the USNO B1.0 optical catalogue. Similarly, we used the CIAO task wavdetect to determine the position and the 90% confidence level error circle using the Chandra data, which is fully consistent with the XMM-Newton results (\(\alpha = 10:46:08.7\), \(\delta = -59:43:06.7\), \(r_{90} = 1.96 \text{ arcsec}\)).

The VLT observations consisted of short exposure (2\(\times\)150 s in each filter) pre-imaging data which had the goal of selecting possible optical candidates for spectroscopy or deeper imag-
The optical images were astrometrically calibrated using non-saturated 2MASS and GSC-2 catalogued stars and the GAIA software. We obtained additional imaging on the source at the Southern Astrophysical Research (SOAR) 4.1 m telescope in V and Hα (6x1120s and 6x1575 s) in February 2008, which also failed to detect any object. In order to compute upper limits for the optical counterpart of XMM J1046, we defined the limiting magnitude of the data as the magnitude of the faintest simulated star still successfully measured by means of PSF fitting, on the exact location of XMM J1046. For all filters, the synthetic star was no longer detected or it was rejected (while trying to fit the PSF model) when the signal-to-noise ratio was worse than 2.5. At this confidence level (98.76%), the present upper limits are $m_V \gtrsim 26$, $m_H \gtrsim 25.5$ and $m_R \gtrsim 25$. Although some structure in the Hα nebular emission is present close to the position of XMM J1046, it is not clear if it is related to XMM J1046 since similar structures also appear in other parts of the nebula, see Fig. 4.

After correcting for photoelectric absorption and interstellar extinction, the above limits imply $\log(F_X/F_V) \gtrsim 3.1^{+0.3}_{-0.1}$. For an assumed $N_H = (3.5 \pm 1.1) \times 10^{21}$ cm$^{-2}$, $A_V \sim 1.96(6)$ (Predehl & Schmitt 1995), and the unabsorbed X-ray flux$^{13}$ is

$$ F_X \sim (1.4^{+2.8}_{-0.8}) \times 10^{-12} \text{ erg s}^{-1} \text{ cm}^{-2} \text{ in the 0.1–12 keV energy band. The high value of the X-ray-to-optical flux ratio practically rules out any other possibility than an INS. For instance, late-type (M, G, K) stars and active galactic nuclei (AGN) show logarithmic X-ray-to-optical flux ratios \sim -1 and within$^{14}$

$\sim 1$ and 1 (e.g. Barcons et al. 2007, and references therein), respectively, while cataclysmic variable (CV) systems and BL Lac objects, which are among the most extreme classes of objects, have $\log(F_X/F_V) \leq 2$ (e.g. Schwope et al. 1999). Obscured T-Tauri stars would exhibit much more absorbed X-ray spectra. We also note that the high total Galactic extinction in the direction of XMM J1046 ($E(B-V) \sim 12$; Schlegel et al. 1998) rules out a background AGN. Moreover, the Parkes-MIT-NRAO Multibeam Survey of the southern hemisphere shows no radio source located at \pm 6 arcmin from the position of XMM J1046 to a flux limit of \sim 32 mJy (Wright et al. 1994). The Parkes Multibeam Pulsar Survey has a sensitivity of about 0.14 mJy for a canonical pulsar (Lyne 2008; Manchester et al. 2005) and also failed to detect the source – the nearest entry in the ATNF Pulsar Catalogue is AXP 1E 1048.1-5937, at \sim 32 arcmin from XMM J1046, and the young radio pulsar PSR J1052-5954, at \sim 50 arcmin.

This, together with its thermal, soft energy distribution, makes XMM J1046 a very promising INS candidate, with overall properties similar to the M7. Deep radio searches and dedicated X-ray and optical observations should be carried out in order to confirm its nature and to determine to which subgroup of INSs it may belong. For comparison, the identification of the M7 RX J12143.0-0654 with an INS was first proposed on the basis of a \sim 500 net counts ROSAT PSPC spectrum and of follow-up optical observations yielding $\log(F_X/F_V) \gtrsim 3$ (Zampieri et al. 2001), the nature of the source was then confirmed by a dedicated XMM-Newton observation (Zane et al. 2005).

3. Discussion

On the basis of the present data, the identification of XMM J1046 with an INS appears convincing. If proven correct, this would be the first example of a presumably radio-quiet and X-ray dim INS, located at a significantly greater distance than the M7.
Most probably, all cooling INSs contained in the ROSAT Bright Source Catalogue have already been identified (Popov et al. 2003; Rutledge et al. 2003), so that new sources must be looked for at lower fluxes. The search for "blank field" sources (Pérez-Azorín et al. 2006; Treves et al. 2007) produced candidates with X-ray-to-optical flux ratios of ~10 to 100. Further X-ray and optical investigations of one such blank field led to the discovery of Calvera, a very large sky close to the Galactic plane (e.g. Treves et al. 2007) produced candidates with X-ray-to-optical fluxes are also expected to be hotter than the M7 (an observation by Posselt et al. 2008) show that, in general, cooling INSs at lower soft X-ray column density is a factor of \(10^3\). The Bondi-Hoyle accretion rate for a star moving through the ISM with particle density \(n = 10^{12} \text{cm}^{-3}\) is \(M = 10^{14} \text{g s}^{-1}\), where \(v = 10 \text{km s}^{-1}\) is the velocity of the neutron star relative to the ISM in units of 10 km s\(^{-1}\). For \(n = 10^{-1} \text{cm}^{-3}\), as appears likely inside the nebula, Bondi-Hoyle accretion can produce the required luminosity but the star should move very slowly through the gas, \(v \approx 10 \text{km s}^{-1}\). Radio pulsars are known to have very high spatial velocity (typically \(v \approx 400 \text{km s}^{-1}\); e.g. Hobsby et al. 2005; Faucher-Giguère & Kaspi 2004), thus the chance to have an object so slow is very small. Moreover, several mechanisms are known to inhibit accretion onto a magnetized INS (Blaes et al. 1995; Toropina et al. 2003; Ikhsanov 2007).

Interestingly, and in agreement with the results of simulations by Posselt et al. (2008), a higher temperature and greater distance respective to the M7 are also observed in the only RRAT (J1819-1458; McLaughlin et al. 2007) detected up to now in X-rays. The XMM-Newton spectrum of J1819-1458 is well fitted by a blackbody with \(kT \approx 140 \text{eV}\) and a broad absorption feature at \(\sim 1 \text{keV} \) similar to that of the M7, which are usually interpreted as evidence for magnetic fields of \(~ 10^{13} - 10^{14} \text{G}\). Its DM distance is \(~ 3.6 \text{kpc} \) and the observed flux is \(F_X \approx 1.5 \times 10^{-13} \text{erg s}^{-1} \text{cm}^{-2} \) (0.3–5 keV). The M7 and this RRAT also share similar spin periods and period derivatives.

Alternative, the rich star forming environment of the Carina Nebula brings in the intriguing possibility that XMM J1046 could be a much older neutron star accreting from the ISM, probably born outside the nebula and whose orbit is presently intersecting the H\(\alpha\) region. We note that, in this case, position and velocity are not expected to be correlated. The gas mass in the Carina Nebula is \(~ 10^6 \text{M}_\odot\) (Smith & Brooks 2007) which, for a typical H\(\alpha\) region size of \(~ 100 \text{pc}\), implies an average density of \(~ 10 \text{cm}^{-3}\). In fact, as reported by Mizutani et al. (2002), two distinct electron density components are detected in a 30 pc area centered on the Carina I and II H\(\alpha\) regions: a high-density (\(n_e \approx 100–350 \text{cm}^{-3}\)) component and an extended low-density (\(n_e \lesssim 100 \text{cm}^{-3}\)) component detectable over the entire mapped region. If XMM J1046 is moving inside the nebula, the corresponding increase on the column density is \(~ 1.5 \times 10^{20} \text{cm}^{-2} \text{pc}^{-1}\), assuming a typical density of \(~ 50 \text{cm}^{-3}\). This means that the source could be up to \(~ 10 \text{pc}\) inside the nebula and \(N_H\) would still be compatible with the measured value and with the one derived for Eta Carinae.

At 2.3 kpc, the luminosity of XMM J1046 is \(L_X \approx (9 \times 10^{33}) \text{erg s}^{-1}\). Although the estimated emission radius of XMM J1046 is comparable to those of the M7, the higher blackbody temperature is responsible for the factor of nearly 10 higher X-ray luminosity. If XMM J1046 is in the accretion phase, mass entrainment should then proceed at a rate \(M = L_X/n_e c^2 \approx 5 \times 10^{12} \text{g s}^{-1}\), where \(n_e \approx 0.2\) is the efficiency. The Bondi-Hoyle accretion rate for a star moving through the ISM with particle density \(n = 10^{11} \text{cm}^{-3}\) is \(M = 10^{14} \text{g s}^{-1}\), where \(v_0\) is the velocity of the neutron star relative to the ISM in units of 10 km s\(^{-1}\). For \(n = 10^{-2} \text{cm}^{-3}\), as appears likely inside the nebula, Bondi-Hoyle accretion can produce the required luminosity but the star should move very slowly through the gas, \(v \sim 10 \text{km s}^{-1}\). Radio pulsars are known to have very high spatial velocity (typically \(v \approx 400 \text{km s}^{-1}\); e.g. Hobsby et al. 2005; Faucher-Giguère & Kaspi 2004), thus the chance to have an object so slow is very small. Moreover, several mechanisms are known to inhibit accretion onto a magnetized INS (Blaes et al. 1995; Toropina et al. 2003; Ikhsanov 2007).

Interestingly, and in agreement with the results of simulations by Posselt et al. (2008), a higher temperature and greater distance respective to the M7 are also observed in the only RRAT (J1819-1458; McLaughlin et al. 2007) detected up to now in X-rays. The XMM-Newton spectrum of J1819-1458 is well fitted by a blackbody with \(kT \approx 140 \text{eV}\) and a broad absorption feature at \(\sim 1 \text{keV} \) similar to that of the M7, which are usually interpreted as evidence for magnetic fields of \(~ 10^{13} - 10^{14} \text{G}\). Its DM distance is \(~ 3.6 \text{kpc} \) and the observed flux is \(F_X \approx 1.5 \times 10^{-13} \text{erg s}^{-1} \text{cm}^{-2} \) (0.3–5 keV). The M7 and this RRAT also share similar spin periods and period derivatives.
On the other hand, steady or transient radio emission are not detected in any of the M7 to a rather sensitive limiting flux of few 10 µJy (Kondratiev et al. 2008). In order to better understand the relations between these two classes of INSs, further, deeper pointings in X-rays and in radio are required to firmly assess the nature of this and other RRAT sources.

4. Summary and conclusions

Overall, the present observational picture of XMM J1046 suggests that it has the right properties to be identified with a younger and more distant thermally emitting INS, possibly the eighth member of the ROSAT-discovered M7. The analysis of its X-ray emission, although based on archival data obtained with non-optimal configurations, reveals an intrinsically soft energy distribution, possibly variable on long time scales. However, uncertainties on the calibration accuracy of the large off-axis angles at which the source was observed may account for the variations of the derived spectral parameters. Its mean temperature, column density and 0.15–3 keV observed flux are •••• 0.3, already high enough to safely exclude standard classes of X-ray emitters (late-type stars, AGN and CVs). The column density is consistent with the source being located within the Carina Nebula, roughly at a distance of •••• kpc. Assuming that the X-ray emission is well described by the mean parameters given above, XMM J1046 may be more luminous and younger than the M7 and thus perhaps still close to its birth place. XMM J1046 is unique in the sense that it is hotter than the seven nearby sources and may represent an evolutionary missing place. XMM J1046 is unique in the sense that it is hotter than the
