(Dated: April 2, 2008)

Urban street patterns form planar networks whose empirical properties cannot be accounted for by simple models such as regular grids or Voronoi tessellations. Striking statistical regularities across different cities have been recently empirically found, suggesting that a general and details-independent mechanism may be in action. We propose a simple model based on a local optimization process combined with ideas previously proposed in studies of leaf pattern formation. The statistical properties of this model are in good agreement with the observed empirical patterns. Our results thus suggests that in the absence of a global design strategy, the evolution of many different transportation networks indeed follow a simple universal mechanism.

PACS numbers: 89.75.-k, 89.75.Kd, 89.65.Lm

Transportation networks —structures that convey energy or matter from one point to another— appear in various different fields, including city streets [1, 2], plant leaves [3], river networks [4], mammalian circulatory systems [5], networks for commodities delivery [6], and technological networks [7]. The recent availability of massive data sets has opened the possibility for quantitative analysis and modeling of these patterns and we focus here on the urban street network. Despite the peculiar geographical, historical, social-economic mechanisms that have shaped distinct urban areas in different ways (see for example [8] and refs. therein), recent empirical studies [1, 9, 10, 11, 12, 13, 14, 15] have shown that, at least at a coarse grained level, unexpected quantitative similarities exist. The simplest description of the street network consists of a graph whose links represent roads, and vertices represent roads’ intersections and end points. For these graphs, links intersect essentially only at vertices and are thus planar. Although the importance of networks in geography and urban modeling has been recognized for a long time [10], comparably less attention has been devoted to generative models for planar graphs in the recent literature on complex networks [17]. Our aim is to propose a simple model for planar graph generation, based on plausible physical assumptions, and which reproduces several empirical findings. In the first part of this paper we discuss the empirical and quantitative signatures that characterize the topology of street patterns and which suggest the possibility to identify some general driving force steering the formation and evolution of street patterns. In the second part, we propose and discuss a simple and parameter-free model based on a principle of local optimality that quantitatively reproduces the above mentioned empirical features. The application of optimality principles to both natural and artificial transportation networks has a long tradition [18] and in most cases requires the minimization of a global cost function (such as the average total time for example), in sharp contrast with the model presented here. The rationale to invoke a local optimality principle in this context is that every new road is built to connect a new location to the existing road network in the most efficient way [19]. The locality of the rule is implemented both in time and space during the evolution and formation of the street network, in order to reflect evolution histories that greatly exceeds the time-horizon of planners. The self-organized pattern of street emerges as a consequence of the interplay of the geometrical disorder and the local rules of optimality.

In [1, 2] measurements for different cities in the world are reported. Based on the data from these sources, we plot in Fig. 1 the number of roads $E$ (edges) versus the number of intersections $N$. The plot is consistent with a linear fit with slope $\approx 1.44$. When individual data points are considered, the quantity $e = E/N = \langle k \rangle / 2$ (where $\langle k \rangle$ is the average degree of a node) shows a range of values $1.05 < e < 1.69$, in between the value $e = 1$ and $e = 2$ that characterize tree-like structures and $2D$ regular lattices, respectively. These values are however not very indicative: planarity imposes severe constraints on the degree of a node and on its distribution which is generally peaked around its average value. Few exact values and bounds are available for the average degree of classical models of planar graphs. In general it is known that $e \leq 3$, while it has been recently shown [20] that $e > 13/7$ for planar Erdős-Rényi graphs [20]. In Fig. 1b, we plot the total length $\ell$ of the network versus $N$ for the towns considered in [1]. Data are well fitted by a power function of the form $\mu N^{0.49}$ with $\mu \approx 1.51$ and $\beta \approx 0.49$. The simplest hypothesis consistent with the data, at this stage, is that of an homogeneous and translational invariant structure. Indeed, a simple scaling argument, that could apply to a large family of planar graphs, including regular lattices, suggests that the typical distance $\ell_1$ between connected nodes scales as $\ell_1 \sim (N/L^2)^{\rho}$, where $\rho = N/L^2$ is the density of vertices and $L$ the linear dimension of the ambient space. This implies for the total
length $\ell \sim E_1 \sim \frac{k}{\mu} L \sqrt{N}$. The discrepancies between the measured $\langle k \rangle$ and $\mu$, given the error bars, are therefore not enough to reject the hypothesis of an almost regular lattice. However, the network of roads naturally produce a set of non-overlapping cells, encircled by the regular lattice. Nevertheless, the network of roads naturally forms factor $\varphi/\alpha$ with $\alpha \approx 1.9$. This is in sharp contrast with the simple picture of an almost regular lattice which would predict a distribution $P(A)$ very peaked around $\ell_2^2$. The authors of [13] also measured the distribution of the form factor $\varphi = 4A/(\pi D^2)$, (the ratio of the area of the cell to the area of the circumscribed circle) and found that most cells have a form factor between 0.3 and 0.6, suggesting a large variety of cell shapes, in contradiction with the assumption of an almost regular lattice. These facts thus call for a model radically different from simple models of regular or perturbed lattices. In the following, we describe a model where the set of ‘centers’ (representing new homes, businesses, etc.) and the network of roads that connects them grow simultaneously. New centers are introduced every $\tau_C > 1$ time steps, and for the purpose of the present study we simply assume that the location of new points is given exogenously and we first assume them to be randomly and uniformly located over a square of given size. Finite segments (of fixed and small length) of roads are simultaneously added to the existing network every $\tau_R = 1 < \tau_C$ in order to account for the limited time horizon of planners. The algorithm that drives the construction of new portions of roads is based on a local optimality principle and aims at connecting to the network the still unconnected centers using as little as possible road-length.

In order to explain the algorithm, we illustrate it on the simple example of Fig. 2. We assume that at a given stage of the evolution, two centers $A$ and $B$ still need to be connected to the network. At any time step, each center can trigger the construction of a single new portion of road of fixed (small) length. In order to maximally reduce their distance to the network, both $A$ and $B$ would select the closest points $M_1$ and $M_2$ in the network as initial points of the new portions of roads to be built. If $M_1$ and $M_2$ are distinct, segments of roads are added along the straight lines $M_1A$ and $M_2B$. If $M_1 = M_2 = M$, it is not economically reasonable to build two different segments of roads and in this case only one single portion $MM'$ of road is allowed. Our main assumption is that the best choice is to build it in order to maximize the reduction of the cumulative distance from the network $(M)$ to $A$ and $B$

$$\Delta = |d(M, A) + d(M, B)| - |d(M', A) + d(M', B)|$$

The maximization of $\Delta$ is done under the constraint $|MM'| = \ll 1$ and a simple calculation leads to

$$MM' \propto \vec{u}_A + \vec{u}_B$$

where $\vec{u}_A$ and $\vec{u}_B$ are the unit vectors from $M$ in the direction of $A$ and $B$ respectively. The rule [2] can easily be extended to the situation where more than two centers want to connect to the same point $M$. Already in this simple setting non trivial geometrical features appear. In the example of Fig. 2 the road from $M$ will develop a bended shape until it reaches the line $AB$ and intersects it perpendicularly as it is commonly observed in most urban settings. At the intersection point, a singularity occurs with $\vec{u}_A + \vec{u}_B \approx 0$ and one is then forced to grow two independent roads from the intersection to $A$ and $B$. The above procedure is iterated until all centers are connected. Interestingly, although the minimum expenditure principle was not used, the rule Eq. [2] was proposed by Runions et al. [3] in a study about leaf venation patterns and we can follow their implementation. In particular, the growth scheme described so far leads to tree-like structures and we implement ideas proposed in [3] in order to create networks with loops. Indeed, even if tree-like structures are on one side economical, on the other hand, they are hardly efficient (for example the path length along a minimum spanning tree scales as a power 5/4 of the Euclidean distance between the endpoints [21]) and better accessibility is granted if loops are present. Following [3], we assume that a new center can trigger the construction of more than one portion of road per time step. An unconnected center $s$ ‘stimulates’ the addition of new portion of roads from any vertex $v$ of the road network (vertices correspond to any end points of the previously introduced road segments) that is in its relative neighborhood [22]. A node $v$ belongs to the relative neighborhood of $s$ if for any node
scales as from a center to the existing road network shortens and time progresses, density increases, and the typical length distribution of new centers are shown for different times. As a blueprint, non-trivial global properties emerge. In Fig. 3 demonstrates that even in the absence of a well defined agreement with empirical data (discussed below) which is the next most important step [25]. Despite this limitation, strong evidences [11, 24] suggest that this is not the case and from the structure of the road network. In fact, strong evidences [11, 24] suggest that this is not the case, and integrating the correlation centers-network is the next most important step [25]. Despite this limitation, the model produces realistic results, in good agreement with facts reported earlier [15]. A simple spatial uniform disorder and a plausible mechanism that connects the centers to the network can thus explain the non-trivial form of the φ factor distribution, but predicts an exponential behavior for the area distribution (Fig. 4), in disagreement with empirical observations [15]. In real cases however, the density of centers is not uniform. We therefore relax this assumption and assume, as supported by a previous empirical study [10], that the centers’ distribution follows the population density and decreases as \( P(r) = \exp(-|r|/r_c) \) where \( r \) is the distance from the central business district and \( 1/r_c \) the population density gradient. Although most quantities (such as \( \langle k \rangle \) and \( \ell \)) are not sensitive to the centers’ distribution, the impact on the area distribution is drastic. Indeed, as shown in Fig. 5 we observe a power law decay with an exponent equal to 1.9 ± 0.05 in remarkable contrast to the exponential decay observed in Fig. 4.

\[
u (\text{center or vertex of the road network}) \text{ the inequality } d(v, s) < \max(d(s, u), d(u, v)) \text{ holds }[23], \text{ which captures the loosely defined requirement that } v \text{ belongs to the relative neighborhood of } s \text{ if the region between } s \text{ and } v \text{ is empty. Centers can therefore be reached by more than one road, leading to the formation of loops. When more than one center stimulates the same point the prescription of Eq. (2) is applied and the evolution ends when the list of stimulated points is exhausted.}

\[
\text{The final road network is achieved starting from a small set of } n_0 \text{ centers connected by roads and iterating the following two steps: (i) at every time multiple of } \tau_C \text{ we add } n \text{ new centers whose locations } r \text{ are chosen randomly according to a given distribution } P(r); \text{ (ii) the road network grows according to the algorithm described above. When a center is reached by all the roads it activated, it becomes 'inactive' and cannot stimulate the growth of a road any longer. We repeat (i-ii) until the total number of centers reaches a desired value. Although it is clear that the focus of the present paper is on the road network growth, it is important to stress that our model relies on a number of simplifying assumptions, the most relevant of which is the fact that the centers are independently located one from the other and from the structure of the road network. In fact, strong evidences [11, 24] suggest that this is not the case, and integrating the correlation centers-network is the next most important step [25]. Despite this limitation, the model produces realistic results, in good agreement with empirical data (discussed below) which demonstrates that even in the absence of a well defined blueprint, non-trivial global properties emerge. In Fig. 3 example of patterns obtained for a spatially uniform distribution of new centers are shown for different times. As time progresses, density increases, and the typical length from a center to the existing road network shortens and scales as \( t_1 \sim 1/\sqrt{p} \sim 1/\sqrt{t} \) as observed in the simulations. Beyond visual similarities with real cities, the ratio \( e = E/N \) has initially a value around 1 (corresponding to a tree-like network) and increases very fast with \( N \) reaching a value around \( e \approx 1.3 \) which is not far from the empirical finding (here and in the following, we checked that the results were robust for different values of the growth rate \( n/\tau_C \)). Consistently, in Fig 4a we observe a relationship between the total length and \( N \) that is well approximated by a function of the form \( a\sqrt{N} \) with \( a \approx 1.90 \), again in reasonable agreement with the empirical data. Panels b, c, and d of Fig. 4 show the collapse for different values of \( N \) of the distributions of \( \phi, A \) and the perimeter \( p \) of the cells, respectively. The excellent collapses show that the structures obtained are consistent with the hypothesis of homogeneity and translational invariance formulated above. We also note that the distribution of the \( \phi \) factor is peaked around 0.6 and essentially supported in the interval \( 0.4 < \phi < 0.7 \), in very good agreement with facts reported earlier [15].

\[
\text{FIG. 3: Snapshots of the network at different times of its evolution: for (a) } t = 100, \text{ (b) } t = 500, \text{ (c) } t = 2000, \text{ (d) } t = 4000 \text{ (the growth rate is here } \eta = 0.1) \text{. At short times, we have almost a tree structure and loops appear for larger density values obtained at larger times (the number of loops then increases linearly with time).}
\]

\[
\text{FIG. 4: Simulation results (averaged over 1000 configurations). (a) Total length of roads versus the number of nodes. The dotted line is a square root fit. (b) Structure factor distribution showing a good agreement with the empirical results of [15]. (c-d) Rescaled distributions of the perimeter (c) and of the areas (d) of the cells displaying an exponential behavior.}
\]
agreement with the empirical result of [15] for the road network of the city of Dresden. This agreement confirms that the simple local optimization is a good candidate for the main process driving the evolution of city street patterns but also shows that the center spatial distribution $P(r)$ is crucial.

More than 50% of the world population lives today in cities and this figure is bound to increase [26]. This migration effect has dictated a fast and short-term planned urban growth which needs to be understood and modeled in terms of socio-geographical contingencies and of the general forces that drive the development of cities. Previous studies about urban morphology have mostly tried to identify specific mechanisms that have shaped distinct urban areas in different ways. Here we studied a simple model based on the assumption that road networks develop trying to grant in an efficient and at the same time economic way connections to a set of ‘centres’. The model accounts quantitatively for a list of descriptors that characterize the topology of street patterns, and in a more qualitative way for the tendency to have bended roads—even in absence of geographical obstacles—and perpendicular intersections. Interestingly, the optimality principle applied here turns out to be general and was implicitly at the basis of a model previously investigated [3] to explain the formation of veins’ patterns in leaves, pointing to an unexpected generality of the principle in the formation of transportation systems. This model is simple enough to allow many interesting generalizations. In particular, our results suggest that the local optimality principle is a key ingredient for a more general model describing the co-evolution of the center distribution and the network [27].
