Diagram rigidity for geometric amalgamations of free groups.

Jean-François Lafont

March 29, 2022

Abstract

In this paper, we show that a class of 2-dimensional locally CAT(-1) spaces is topologically rigid: isomorphism of the fundamental groups is equivalent to the spaces being homeomorphic. An immediate application of this result is a diagram rigidity theorem for certain amalgamations of free groups. The direct limit of two such amalgamations are isomorphic if and only if there is an isomorphism between the respective diagrams.

1 Introduction.

In this paper, we introduce the notion of a geometric amalgamation of free groups. This is a class of diagrams of groups, with the property that they are rigid in the following sense:

Theorem 1.1 (Diagram rigidity). Let \( \mathcal{G}_1, \mathcal{G}_2 \) be a pair of geometric amalgamations of free groups. Then \( \lim \mathcal{G}_1 \) is isomorphic to \( \lim \mathcal{G}_2 \) if and only if \( \mathcal{G}_1 \) is isomorphic to \( \mathcal{G}_2 \) (as diagrams of groups).

In order to prove this theorem, we will first translate the question to a more topological setting. Associated to any geometric amalgamation of free groups, there is a canonically defined topological space, which we call a simple, thick, 2-dimensional hyperbolic P-manifold. The associated space will have fundamental group isomorphic to the direct limit of the geometric amalgamation, and has the property that the diagram can be “read off” from the topology of the space. The first theorem will then be a consequence of the following purely topological result:

Theorem 1.2 (Topological rigidity). Let \( X_1, X_2 \) be a pair of simple, thick, 2-dimensional hyperbolic P-manifolds, and assume that \( \phi : \pi_1(X_1) \to \pi_1(X_2) \) is an
isomorphism. Then there exists a homeomorphism $\Phi : X_1 \to X_2$ that induces $\phi$ on the level of the fundamental groups.

Immediate applications of this second theorem are the following:

**Corollary 1.1 (Nielsen realization).** Let $X$ be a simple, thick, 2-dimensional hyperbolic $P$-manifold. Then the canonical map from $\text{Homeo}(X)$ to $\text{Out}(\pi_1(X))$ is surjective.

**Corollary 1.2 (co-Hopf property).** Let $\mathcal{G}$ be a geometric amalgamation of free groups. Then $\varprojlim \mathcal{G}$ is a co-Hopfian group.

We note that the second corollary can also be obtained from work of Sela [11], who proved that a non-elementary torsion-free $\delta$-hyperbolic groups is co-Hopfian if and only if it is freely indecomposable.

The proof of Theorem 1.2 relies on a topological characterization of certain points in the boundary at infinity of the universal cover of a simple, thick, 2-dimensional hyperbolic $P$-manifold (these spaces are $\text{CAT}(-1)$).

## 2 Some preliminaries.

In this section, we briefly define the various notions that are relevant to this paper, and recall some basic facts that will be used in the proofs.

**Definition 2.1.** For our purposes, a **diagram of groups** $\mathcal{G}$ will consist of:

- a finite connected directed graph, which we will also denote by $\mathcal{G}$, with vertex set $V(\mathcal{G})$ and directed edges $E(\mathcal{G})$,
- an assignment of a group $G_v$ to each vertex $v \in V(\mathcal{G})$
- an assignment of a homomorphism $\phi_e : G_{e_-} \to G_{e_+}$ to each directed edge $e \in E(\mathcal{G})$, where $e_-$ and $e_+$ denote the initial and terminal endpoints of the directed edge $e$.

We will denote by $\varprojlim \mathcal{G}$ the direct limit of the diagram $\mathcal{G}$.

Observe that the above definition differs superficially from the notion of a graph of groups used in Bass-Serre theory (see for instance Serre [12]). The interested reader can easily translate the above definition into the language of Bass-Serre theory. We now refine the above definition to the diagrams we are really interested in:
Definition 2.2. We will say that a diagram of groups $G$ is a *geometric amalgamation of free groups* provided it satisfies the following properties:

- the vertex set $V(G)$ can be partitioned into $V_0(G)$ and $V_1(G)$, and every directed edge $e \in E(G)$ has $e_- \in V_0(G)$, $e_+ \in V_1(G)$. Furthermore, each vertex in $V_0(G)$ has degree at least three.

- the group associated to every $v \in V_0(G)$ is isomorphic to $\mathbb{Z}$, and the group associated to every $w \in V_1(G)$ is a free group with rank $\geq 2$.

- associated to every $w \in V_1(G)$, there is a compact surface $M_w$ whose fundamental group is $G_w$.

- each edge morphism $\phi_e$ maps $G_{e_-} \cong \mathbb{Z}$ isomorphically onto a group conjugate to the fundamental group of a boundary component in $G_{e_+} \cong \pi_1(M_{e_+})$.

- for every vertex $w \in V_1(G)$, and every conjugacy class of $\mathbb{Z}$-subgroups of $G_w \cong \pi_1(M_w)$ corresponding to a boundary component of $M_w$, there is precisely one edge $e \in E(G)$ with $e_+ = w$, and $\phi_e(G_{e_-})$ lying within the conjugacy class.

More concisely, we can think of a geometric amalgamation of free groups as being a diagram of groups consisting of two rows:

```
Z   Z   Z   Z   \cdots
\uparrow \uparrow \uparrow \uparrow \cdots
F_{k_1} \rightarrow F_{k_2} \rightarrow F_{k_3} \rightarrow F_{k_4} \rightarrow \cdots
```

where each $\mathbb{Z}$ group in the bottom row injects into at least three of the free groups in the top row, and has image lying in a “boundary subgroup” of the free groups in the top row. In addition, each “boundary subgroup” in the top row lies in the image of precisely one $\mathbb{Z}$ from the bottom row (upto conjugacy).

Now the main motivation behind our terminology lies in that the direct limit of a geometric amalgamation of free groups naturally corresponds to the fundamental group of an associated topological space. We now proceed to define these spaces.

Definition 2.3. We say that a compact geodesic metric space $X$ is a simple, thick, 2-dimensional hyperbolic $P$-manifold, provided that there exists a closed subset $Y \subset X$ with the property that:

- each connected component of $Y$ is homeomorphic to $S^1$, and forms a totally geodesic subspace of $X$. 
• the closure of each connected component of $X - Y$ is homeomorphic to a compact surface with boundary, and the homeomorphism takes the component of $X - Y$ to the interior of the surface with boundary; the closure of such a component will be called a chamber.

• there exists a hyperbolic Riemannian metric on each chamber which coincides with the original metric.

• each connected component of $Y$ lies in the closure of at least three distinct chambers.

We will call the subset $Y$ the branching locus, and will call the connected components of $Y$ branching geodesics.

Note that simple, thick, 2-dimensional hyperbolic $P$-manifolds are locally CAT(-1) (see [2]), and hence their universal covers are CAT(-1) spaces. In particular, this implies that their fundamental groups are $\delta$-hyperbolic groups, and that an abstract isomorphism between the fundamental groups of two such spaces naturally induces a quasi-isometry between their universal covers.

To make precise the correspondence between the previous two definitions, we show the following:

Lemma 2.1. A group $G$ is the fundamental group of a simple, thick, 2-dimensional hyperbolic $P$-manifold if and only if it is the direct limit of a geometric amalgamation of free groups.

Proof. If $G$ is the fundamental group of a simple, thick, 2-dimensional hyperbolic $P$-manifold $X$, we consider an open cover $\{U_i\}$ of $X$ by open sets which consist of $\epsilon$-neighborhoods of the chambers of $X$, where $\epsilon$ is chosen to be small enough. An immediate application of the general form of the Siefert-Van Kampen Theorem (see Chapter 2, Section 7 in May [7]) that the fundamental group of $X$ is isomorphic to the direct limit of a diagram of groups obtained from the covering $\{U_i\}$. Furthermore, the diagram has vertex groups isomorphic to the fundamental groups of the various intersections of open sets in the covering $\{U_i\}$, with edge morphisms induced by inclusions. It is immediate that for the covering we’ve defined, the resulting diagram is a geometric amalgamation of free groups. Furthermore, the diagram is uniquely defined by the space $X$.

Conversely, assume that $G$ is the direct limit of a geometric amalgamation of free groups, denoted by $\mathcal{G}$. Corresponding to the diagram $\mathcal{G}$, we can associate a diagram of topological spaces by associating to each vertex in $v \in V_0$ an $S^1$, and to each vertex $w \in V_1$ the corresponding compact surface with boundary $M_w$. Note that to each edge, there corresponds a homeomorphism from one of the $S^1$ (corresponding to the
initial vertex of the edge) to a boundary component of one of the $M_w$ (corresponding to the terminal vertex of the edge). Now consider the direct limit of this diagram of spaces in the category of topological spaces. It is immediate that this direct limit is a simple, thick, 2-dimensional P-manifold $X$, and, by the discussion in the previous paragraph, that $\pi_1(X) \cong G$.

To conclude, we need to show that $X$ supports a hyperbolic metric. To see this, we make each $S^1$ isometric to the unit circle in $\mathbb{R}^2$, and make each $M_w$ isometric to a compact hyperbolic surface with all boundary components totally geodesic of length $2\pi$. We further require the homeomorphisms from the $S^1$ to the boundary components of the $M_w$ to be isometries. This immediately yields a hyperbolic metric on the P-manifold $X$.

Finally, we point out that the space $X$ constructed above is unique up to homeomorphism. This follows from the fact that if $M$ is a compact orientable surface with boundary, and $\phi : \partial M \to \partial M$ is an orientation preserving self-homeomorphism, then there is a self-homeomorphism $\hat{\phi} : M \to M$ that induces $\phi$ when restricted to the boundary. In particular, the choice of homeomorphisms used to identify the various $S^1$ (corresponding to the $\mathbb{Z}$ groups) with the boundary components of the $M_w$ (corresponding to the free groups) does not influence the topology of the resulting space.

Finally, to conclude this section, we reduce the proof of Theorem 1 to that of Theorem 2:

*Proof (Diagram Rigidity).* Let us start with a pair $\mathcal{G}_1, \mathcal{G}_2$ of geometric amalgamations of free groups, and assume that $\operatorname{lim} \mathcal{G}_1$ is isomorphic to $\operatorname{lim} \mathcal{G}_2$. From the previous Lemma, we can associate to each $\mathcal{G}_i$ a simple, thick, 2-dimensional hyperbolic P-manifold $X_i$, with the property that $\pi_1(X_i) \cong \operatorname{lim} \mathcal{G}_i$. In particular, the isomorphism between direct limits yields an isomorphism $\phi : \pi_1(X_1) \to \pi_1(X_2)$. From the topological rigidity result, there is a homeomorphism $\Phi : X_1 \to X_2$ which induces $\phi$ on the level of fundamental groups.

Now note that $\Phi$, being a homeomorphism, must map the branching locus in $X_1$ homeomorphically to the branching locus in $X_2$, and hence maps the chambers of $X_1$ homeomorphically to the chambers of $X_2$. Furthermore, the map $\Phi$ induces a bijection between the chambers in $X_1$ and those in $X_2$. But by the uniqueness portion of the Lemma above, this implies that the diagrams $\mathcal{G}_1$ and $\mathcal{G}_2$ are isomorphic, concluding our proof.
3 Topological rigidity.

In this section, we provide a proof of Theorem 1.2. Let us start by fixing some notation. \( X \) will always denote a simple, thick, 2-dimensional hyperbolic P-manifold, \( \tilde{X} \) the universal cover of \( X \), and \( \partial^\infty \tilde{X} \) the boundary at infinity of \( \tilde{X} \). We will let \( \Gamma \) denote the fundamental group of \( X \), \( G \) will denote the collection of geodesics in \( \tilde{X} \), and \( BG \subset G \) will denote the collection of lifts of branching geodesics in \( \tilde{X} \). We will let \( \mathcal{C} \) denote the collection of lifts of chambers in \( \tilde{X} \). Finally, we will let \( \partial^\infty BG \subset \partial^\infty \tilde{X} \) be the collection of points of the form \( \gamma(\pm \infty) \) where \( \gamma \in BG \). In the portions of this section where we deal with a pair of simple, thick, 2-dimensional hyperbolic P-manifolds, we will append subscripts to keep track of which of the two spaces we are referring to.

The first step in our argument consists of identifying the separation properties of individual points in \( \partial^\infty \tilde{X} \). We start with an easy:

**Lemma 3.1.** The boundary at infinity \( \partial^\infty \tilde{X} \) is path-connected.

**Proof.** To see this, let \( p_1, p_2 \in \partial^\infty \tilde{X} \) be an arbitrary pair of points. Let \( \gamma \) be a geodesic in \( \tilde{X} \) satisfying \( \gamma(-\infty) = p_1, \gamma(\infty) = p_2 \). The simplicity and thickness hypotheses on \( X \) ensure that there exists an isometrically embedded \( f: \mathbb{H}^2 \hookrightarrow \tilde{X} \) with the property that \( \gamma \subset \mathbb{H}^2 \). In particular, we see that the pair of points \( p_1, p_2 \) lie on an embedded \( S^1 = \partial^\infty \mathbb{H}^2 \hookrightarrow \partial^\infty \tilde{X} \). Hence there exists a path in \( \partial^\infty \tilde{X} \) joining \( p_1 \) to \( p_2 \), concluding the proof of the Lemma.

Let us recall some basic definitions. A subset \( S \) in a topological space \( X \) is said to **locally separate** provided there exists a neighborhood \( N \) of \( S \) with the property that \( N - S \) is disconnected. If there exists a neighborhood \( N \) such that \( N - S \) consists of \( \geq m \) connected components, we say that \( S \) locally separates into \( \geq m \) components. We say that \( S \) locally separates into \( M \) components provided \( M \) is the supremum of the integers \( m \) with the property that \( S \) locally separates into \( \geq m \) components. We will be interested in the case where \( S \) consists either of a single point, or of a pair of points.

In the case where \( S = \{ x \} \), and \( S \) locally separates the space \( X \), we will say that \( x \) is a **local cutpoint** of \( X \). If in addition \( X - \{ x \} \) is disconnected, will say that the point \( x \) is a **global cutpoint** of \( X \).

We observe that the previous Lemma in particular implies that \( \partial^\infty \tilde{X} \) is connected. From the work of Bowditch [1] and Swarup [13], this immediately yields:

**Corollary 3.1.** The boundary at infinity \( \partial^\infty \tilde{X} \) does not contain any global cutpoints.

We note that the previous Corollary tells us that the **global** separation properties of individual points in \( \partial^\infty \tilde{X} \) are uninteresting. On the other hand, the **local** separation
3 TOPOLOGICAL RIGIDITY.

properties of points in $\partial^\infty \tilde{X}$ are quite interesting. Our next step is to consider a notion which is slightly weaker than “local separation into $\geq 3$ components”.

We now collect some basic facts concerning separation and connectedness properties in simple, thick, hyperbolic P-manifolds. The proofs of the following four lemmas can be found in [5] in the 3-dimensional setting, but the arguments given there extend verbatim to the 2-dimensional setting.

**Lemma 3.2 (Lemma 2.1 in [5]).** Let $\gamma \in \mathcal{BG}$ be a branching geodesic in $\tilde{X}$, and let $C_1, C_2 \in \mathcal{C}$ be two lifts of chambers which are both incident to $\gamma$. Then $C_1 - \gamma$ and $C_2 - \gamma$ lie in different connected components of $\tilde{X} - \gamma$.

**Lemma 3.3 (Lemma 2.2 in [5]).** Let $C \in \mathcal{C}$ be a lift of a chamber, and let $\gamma_1, \gamma_2 \in \mathcal{BG}$ be two branching geodesics which are both incident to $C$. Then $\gamma_1$ and $\gamma_2$ lie in different connected components of $\tilde{X} - \text{Int}(C)$.

**Lemma 3.4 (Lemma 2.3 in [5]).** Let $\{\gamma(\pm \infty)\}$ be the pair of points in $\partial^\infty \tilde{X}$ corresponding to some $\gamma \in \mathcal{BG}$, and let $\partial^\infty C_1, \partial^\infty C_2$ be the boundaries at infinity of two lifts of chambers $C_1, C_2 \in \mathcal{C}$ which are both incident to $\gamma$. Then $\partial^\infty C_1 - \{\gamma(\pm \infty)\}$ and $\partial^\infty C_1 - \{\gamma(\pm \infty)\}$ lie in different connected components of $\partial^\infty \tilde{X} - \{\gamma(\pm \infty)\}$.

**Lemma 3.5 (Lemma 2.4 in [5]).** Let $\partial^\infty C$ be the boundary at infinity corresponding to a connected lift of a chamber $C \in \mathcal{C}$, and let $\{\gamma_1(\pm \infty)\}, \{\gamma_2(\pm \infty)\}$ be the boundary at infinity of two branching geodesics $\gamma_1, \gamma_2 \in \mathcal{BG}$ which are both incident to $C$. Then $\{\gamma_1(\pm \infty)\}$ and $\{\gamma_2(\pm \infty)\}$ lie in different connected components of $\partial^\infty \tilde{X} - (\partial^\infty C - \cup \partial^\infty \eta_i)$, where the union is over all $\eta_i \in \mathcal{BG}$ which are boundary components of $C$.

We define the **tripod** to be the space $T$ obtained by taking the cone of a 3-point set. The cone point will be denoted by $* \in T$. We say that a point $x$ is a **branching point** in a topological space $X$ provided there exists an injective map $f : T \to X$ satisfying $f(*) = x$. It is easy to see that if a point $x$ in a geodesic space $X$ locally separates into $\geq 3$ components, then the point $x$ is a branching point in $X$. The notion of branching was introduced by the author in [5], [6] in order to study the local topology of the boundary at infinity of simple, thick hyperbolic P-manifolds. The proof of the following Proposition closely parallels the arguments given in the paper [5]:

**Proposition 3.1.** For a point $p \in \partial^\infty \tilde{X}$, we have that $p$ is branching if and only if $p = \gamma(\infty)$ for some branching geodesic $\gamma \in \mathcal{BG}$.

**Proof.** We first observe that one implication in the Proposition is immediate: if $p = \gamma(\infty)$ for some branching geodesic $\gamma \in \mathcal{BG}$, then $p$ is branching. So let us focus on the converse.
Assume that \( p \in \partial^\infty \tilde{X} \) is a branching point, and that \( p \) is not a limit point of any branching geodesic. Let \( \gamma \) be a geodesic ray with \( \gamma(\infty) = p \), and observe that for the geodesic ray \( \gamma \) we have either:

1. \( \gamma \) passes through finitely many lifts of chambers, or
2. \( \gamma \) passes through infinitely many lifts of chambers.

For each of the two cases above, we need to show that \( p \) cannot be branching. We argue by contradiction. Assume that \( f : T \to \partial^\infty \tilde{X} \) be an injective mapping of the tripod into \( \partial^\infty \tilde{X} \), satisfying \( f(*) = p \).

Case 1: Since \( \gamma \) passes through finitely many lifts of chambers, and since the lifts of chambers are totally geodesic subsets of \( \tilde{X} \), we have that there exists a fixed lift \( C \) of a chamber with the property that \( \gamma(t) \in C \) for all \( t \) sufficiently large. Now pick a basepoint \( x \) in the interior of \( C \), and pick \( \epsilon \) small enough so that the \( \epsilon \) metric ball \( B_\epsilon(x) \) centered at \( x \) is contained entirely in the interior of \( C \). Denote by \( lk(x) \) the boundary of this metric ball, and observe that \( lk(x) \) is homeomorphic to \( S^1 \).

Let \( \rho : \partial^\infty \tilde{X} \to lk(x) \) be the geodesic projection, and consider the composite map \( \rho \circ f : T \to lk(x) \cong S^1 \).

We first note that there is no injective map from \( T \) to \( S^1 \), hence the composite \( \rho \circ f \) must fail to be injective at some point. Let \( I \subset S^1 \) be the subset of points in \( lk(x) \) where the map \( \rho \) is injective. Our goal is now to show that the composite \( \rho \circ f \) fails to be injective at some point \( z \in I \). This immediately implies that \( f \) fails to be injective at the point \( \rho^{-1}(z) \), which would yield the desired contradiction.

Let us start by observing that \( I \) consists of a Cantor set in \( S^1 \). Indeed, if a point \( w \) lies in the complement of \( I \), then there exist a pair of geodesic rays \( \gamma_1, \gamma_2 \) emanating from \( x \), both of which pass through \( w \in lk(x) \), but satisfying \( \gamma_1(\infty) \neq \gamma_2(\infty) \). In particular, the geodesic rays \( \gamma_1, \gamma_2 \) must coincide for a period of time, and subsequently diverge. This implies that \( \gamma_i \cap \partial C \neq \emptyset \). Hence the point \( w \) lies in the image \( \tilde{\rho}(\partial C) \) of \( \partial C \) under the geodesic retraction map \( \tilde{\rho} : \tilde{X} - B_\epsilon(x) \to lk(x) \).

Conversely, given a point \( w \) in \( \tilde{\rho}(\partial C) \), one can easily construct a pair of geodesic rays \( \gamma_1, \gamma_2 \) originating from \( x \), passing through \( w \), but having \( \gamma_1(\infty) \neq \gamma_2(\infty) \). This forces the complement of \( I \) to coincide with the set \( \tilde{\rho}(\partial C) \). But the complement of the set \( \tilde{\rho}(\partial C) \) can naturally be identified with \( \partial^\infty C \). Since \( C \) is the universal cover of a compact negatively curved surface with non-empty boundary, it is quasi-isometric to a free group \( F_k \). This implies that \( I \) is homeomorphic to \( \partial^\infty F_k \), which is known to be a Cantor set.

Now observe that the complement of the set \( I \subset lk(x) \) consists of a countable dense union of open intervals. Let \( I_\partial \subset I \) denote the subset of \( I \) consisting of the boundary points of these intervals. Note that, by the discussion above, the set \( I_\partial \)
coincides with the set $\rho(\partial^\infty(\partial C))$, and since we are assuming that the point $p \in \partial^\infty X$ is not the limit point of a branching geodesic, we have that $(\rho \circ f)(*) = \rho(p) \in I - I_\partial$.

Let $L_i \cong [0,1]$ $(1 \leq i \leq 3)$ denote the three components of $T - *$, which we will call the open leaves of the tripod $T$. Since $(\rho \circ f)(*) \in I$, we have that $(\rho \circ f)(*) \notin (\rho \circ f)(L_i)$ for each $i$. Let $U$ denote a small open connected neighborhood of $(\rho \circ f)(*)$ in $lk(x) \cong S^1$, and observe that $(\rho \circ f)(*)$ locally separates $U$ into a pair of open intervals $U_1, U_2$. If $U$ is chosen small enough, we must have that a pair of leaves surjects onto one of the $U_j$. We assume, without loss of generality that $U_1 \subset (\rho \circ f)(L_1) \cap (\rho \circ f)(L_2)$. But now we note that in the Cantor set $I$, every point in $I - I_\partial$ can be approximated on both sides by points in $I_\partial$. This implies that $[(\rho \circ f)(L_1) \cap (\rho \circ f)(L_2)] \cap I_\partial \neq \emptyset$, and as $\rho$ is injective on $I_\partial$, that there exist a pair of points $q_1 \in L_1, q_2 \in L_2$ with $f(q_1) = f(q_2) \in \partial^\infty X$. But this contradicts the fact that $f$ is injective, concluding the proof for the first case.

**Case 2:** For the second case, we assume that $\gamma$ is a geodesic ray with $\gamma(\infty) = p$, and which passes through infinitely many lifts of chambers. Note that this forces the geodesic ray $\gamma$ to intersect infinitely many branching geodesics. Let $\{\eta_i\}$ be the collection of branching geodesics intersected by $\gamma$, indexed in the order in which their intersections occur along $\gamma$. We now recall two facts:

1. each $\partial^\infty \eta_i$ separates $\partial^\infty \tilde{X}$ (Lemma 3.4 above), and

2. if $U_i$ denotes the path-connected component of $\partial^\infty \tilde{X} - \partial^\infty \eta_i$ containing $p$, then the collection $\{U_i\}$ forms an open, path-connected, neighborhood base of $p$ in $\partial^\infty \tilde{X}$ (see the proof of Proposition 2.3 in [3]).

Armed with these two facts, the argument for Case 2 is easy: let $L_i \cong [0,1]$ again denote the three open leaves of the tripod. Since $f : T \to \partial^\infty \tilde{X}$ is injective, we have that $p \notin f(\partial T)$, and hence there exists a small enough neighborhood $\tilde{N}$ of $p$ with the property that $f(\partial T) \subset \partial^\infty \tilde{X} - \tilde{N}$. From Fact (2) above, we have that $U_i \subset \tilde{N}$ for $i$ sufficiently large, and hence that $f(\partial T) \subset \partial^\infty \tilde{X} - \tilde{N}$. From Fact (1) above, we have that the corresponding $\partial^\infty \eta_i = \{\eta_i(\pm \infty)\}$ separates $f(\partial T)$ from $p$. But this implies that, for each $1 \leq i \leq 3$, we have that $f(L_i) \cap \{\eta_i(\pm \infty)\} \neq \emptyset$. The pigeon-hole principle forces the image of a pair of leaves to pass through one of the two points $\{\eta_i(\pm \infty)\}$. But this contradicts the fact that $f$ is injective, concluding the argument for Case 2, and completing the proof of the Proposition.

We observe an immediate corollary of the above proposition:

**Corollary 3.2.** If $f : \tilde{X}_1 \to \tilde{X}_2$ is a quasi-isometry, and $f_\infty : \partial^\infty \tilde{X}_1 \to \partial^\infty \tilde{X}_2$ the induced map on the boundary at infinity. Then $f_\infty$ restricts to a bijection from $\partial^\infty BG_1$ to $\partial^\infty BG_2$. 

3 TOPOLOGICAL RIGIDITY.

Proof. Note that the induced map \( f_\infty : \partial_\infty \bar{X}_1 \to \partial_\infty \bar{X}_2 \) is a homeomorphism. But the previous Proposition characterizes the subsets \( \partial_\infty \mathcal{B} \mathcal{G}_i \subset \partial_\infty \bar{X}_i \) purely topologically, yielding the corollary.

We would now like to focus on the specific situation at hand, namely we will assume that we are given a pair \( X_1, X_2 \) of simple, thick, 2-dimensional hyperbolic P-manifolds, and an abstract isomorphism \( \phi \) from \( \Gamma_1 := \pi_1(X_1) \) to \( \Gamma_2 := \pi_1(X_2) \). We observe the following facts that hold in this setting:

- the groups \( \Gamma_i \) act by homeomorphisms on \( \partial_\infty \bar{X}_i \),
- the isomorphism \( \phi \) induces a quasi-isometry \( \bar{\phi} \) from \( \bar{X}_1 \) to \( \bar{X}_2 \),
- the quasi-isometry \( \bar{\phi} \) induces a homeomorphism \( \partial_\infty \bar{\phi} : \partial_\infty \bar{X}_1 \to \partial_\infty \bar{X}_2 \) which is equivariant with respect to the \( \Gamma_i \) actions on the \( \partial_\infty \bar{X}_i \).

The previous corollary tells us that \( \partial_\infty \bar{\phi} \) restricts to a bijection between from the set \( \partial_\infty \mathcal{B} \mathcal{G}_1 \) to the set \( \partial_\infty \mathcal{B} \mathcal{G}_2 \). Now notice that any branching geodesic \( \gamma \in \mathcal{B} \mathcal{G}_1 \) naturally corresponds to a pair of points \( \{ \gamma(\pm\infty) \} \subset \partial_\infty \mathcal{B} \mathcal{G}_1 \). We would like to ensure that, under our homeomorphism \( \phi_\infty \), the pair \( \{ \gamma(\pm\infty) \} \) maps to a pair \( \{ \gamma'(\pm\infty) \} \) for some branching geodesic \( \gamma' \in \mathcal{B} \mathcal{G}_2 \). In order to achieve this, our next step is to characterize the endpoints of branching geodesics in a purely topological manner. This is the content of our:

**Proposition 3.2.** Let \( \{ p, q \} \subset \partial_\infty \mathcal{B} \mathcal{G} \subset \partial_\infty \bar{X} \) be an arbitrary pair of distinct points. Then we have that:

1. if there exists a \( \gamma \in \mathcal{B} \mathcal{G} \) with the property that \( \{ \gamma(\pm\infty) \} = \{ p, q \} \), then \( \{ p, q \} \) separates \( \partial_\infty \bar{X} \) into \( \geq 3 \) components.

2. if there exists a geodesic \( \gamma \) contained in the interior of a single lift of a chamber, with the property that \( \{ \gamma(\pm\infty) \} = \{ p, q \} \), then \( \{ p, q \} \) separates \( \partial_\infty \bar{X} \) into exactly 2 components.

3. in all other cases, \( \{ p, q \} \) does not separate \( \partial_\infty \bar{X} \).

**Proof.** Statement (1) is an immediate consequence of Lemma 3.4 and the thickness hypothesis.

To see statement (2), one starts with a \( \gamma \notin \mathcal{B} \mathcal{G} \), and satisfying \( \gamma \subset \text{Int}(C) \) with \( C \in \mathcal{C} \). Note that this implies that \( \gamma \) separates \( C \) into precisely two open components, denoted \( Z_1 \) and \( Z_2 \). Furthermore, the closure of each component is a closed, totally geodesic subset of \( \bar{X} \). Now for \( i = 1, 2 \), define the sets \( (Z_i)_j \) \( (j \geq 1) \) inductively by:

- the initial condition \( (Z_i)_1 = Z_i \), and
• $(Z_i)_{j+1}$ is the union of $(Z_i)_j$ along with all lifts of chambers which are incident to $(Z_i)_j$.

We observe that we have proper inclusions $(Z_i)_j \subset (Z_i)_{j+1}$, and that each of the subsets $(Z_i)_{j}$ is totally geodesic and path-connected.

Now form the sets $Y_i := \bigcup_{j \in \mathbb{N}} (Z_i)_j$, and observe that each $Y_i$ is a path-connected, totally geodesic subspace of $\tilde{X}$ (as the latter properties are preserved under increasing unions). Furthermore each of the sets $Y_i$ has the property that $\partial^i Y_i - \{\gamma(\pm\infty)\}$ is path-connected. Indeed, given a pair of points in $\partial^i Y_i$, one can consider the geodesic $\eta$ corresponding to the pair of points. It is easy to see that there is an isometrically embedded, totally geodesic “half-$\mathbb{H}^2$” $H \subset Y_i$ with boundary the given geodesic $\eta$. This implies that there exists $\partial^i H \cong \mathbb{I} \subset \partial^i Y_i - \{\gamma(\pm\infty)\}$ whose endpoints correspond precisely to $\{\eta(\pm\infty)\}$.

Finally, observe that $\tilde{X} - \gamma = Y_1 \bigsqcup Y_2$, and that the closure of $Y_i$ is precisely $Y_i \cup \gamma$. Hence we have that $\partial^i \tilde{X} = \partial^i Y_1 \cup \{\gamma(\pm\infty)\} \partial^i Y_2$, expressing $\partial^i \tilde{X}$ as a union of a pair of closed sets (as each $Y_i$ is totally geodesic) whose intersection is precisely $\{\gamma(\pm\infty)\}$, and with the property that each $\partial^i Y_i - \{\gamma(\pm\infty)\}$ is path-connected. This immediately implies statement (2) of the proposition.

So we are now left with showing statement (3). In order to do this, we first make two observations concerning branching geodesics. Note that if $\rho \in \mathcal{BG}$, then we have that $\partial^i \tilde{X} - \{\rho(\pm\infty)\}$ splits into $k \geq 3$ path-connected components $U_1, \ldots, U_k$. We now observe:

**Fact 1:** The closure of each $U_i$ is $\bar{U}_i = U_i \cup \{\rho(\pm\infty)\}$, and is path-connected.

**Fact 2:** For every pair of distinct points $x, y \in Y_i$ there is a path $\eta_x \subset \bar{U}_i - y$ joining $x$ to one of the points $\{\rho(\pm\infty)\}$.

Now assuming these two facts, we proceed with the proof of statement (3). For the points $\{p, q\}$ satisfying the hypotheses of statement (3), we have that the geodesic $\gamma$ satisfying $\gamma(\pm\infty) = \{p, q\}$ must intersect a branching geodesic $\rho \in \mathcal{BG}$. Upto re-indexing, we may assume that $p \in U_1$, and $q \in U_2$.

Now pick an arbitrary pair of points $\{x, y\} \subset \partial^i \tilde{X} - \{p, q\}$, and consider the subsets $U_i, U_j$ satisfying $x \in U_i$, $y \in U_j$. If $i \geq 3$, then from **Fact 1**, there exists a path in $\bar{U}_i$ joining $x$ to $\rho(\infty)$. On the other hand, if $i = 1, 2$, then from **Fact 2**, there is a path joining $x$ to one of the points $\rho(\pm\infty)$, avoiding the point $p$ (if $i = 1$) or $q$ (if $i = 2$). In either case, denote this path by $\eta_x$. Now applying the same reasoning to $y$, we find a path $\eta_y$ joining $y$ to one of the points $\rho(\pm\infty)$, and avoiding the pair $\{p, q\}$.

If the endpoints of the paths $\eta_x, \eta_y$ coincide, concatenation gives us a path connecting $x$ to $y$. Otherwise, from **Fact 1**, we note that there is a path $\eta_p$ in $Y_3$ joining $\rho(\infty)$ to $\rho(-\infty)$. Concatenating the three paths $\eta_x, \eta_p$, and $\eta_y$ yields a path joining $x$ to $y$. 

**3 TOPOLOGICAL RIGIDITY.**
to \( y \) in \( \partial^\infty \tilde{X} - \{ p, q \} \). Since this holds for arbitrary \( x, y \in \partial^\infty \tilde{X} - \{ p, q \} \), we conclude that \( \partial^\infty \tilde{X} - \{ p, q \} \) is path-connected. So to complete the proof of the Proposition, we are left with verifying Fact 1 and Fact 2.

To see Fact 1, we first note that the complement of \( U_i \cup \{ \rho(\pm \infty) \} \) consists of the union \( \bigsqcup_{j \neq i} U_j \). Since all the \( U_j \) are open, this implies that the closure of \( U_i \) is contained in the set \( U_i \cup \{ \rho(\pm \infty) \} \). To see the converse, we observe that we can construct, as in the argument for statement (2), totally geodesic subspaces \( Y_i \) with the property that \( \partial^\infty Y_i = U_i \cup \{ \rho(\pm \infty) \} \) and with \( \partial Y_i = \rho \). But within the \( Y_i \), it is easy to see that there exist totally geodesic embedded ‘half’ \( \mathbb{H}^2 \)'s whose boundary is precisely \( \rho \). At the level of the boundary at infinity, this yields an embedded interval in \( U_i \cup \{ \rho(\pm \infty) \} \) with endpoints precisely \( \{ \rho(\pm \infty) \} \). This immediately implies that \( \{ \rho(\pm \infty) \} \) lies in the closure of the \( U_i \), completing the proof of Fact 1.

To see Fact 2, we note that given \( p \in U_i \), the embedded interval \( f : I \hookrightarrow U_i \cup \{ \rho(\pm \infty) \} \) mentioned in the previous paragraph can be chosen to satisfy \( f(0) = \rho(+\infty), f(1) = \rho(-\infty) \), and \( f(1/2) = p \). Now note that if \( q \notin f(I) \), we are done. On the other hand, if \( q \in f(I) \), then the hypothesis that \( p \neq q \) ensures that \( q = f(r) \) where either \( 0 < r < 1/2 \) or \( 1/2 < r < 1 \). In both cases we can use \( f \) restricted to a suitable subinterval of \( I \) to get the desired path. This completes the proof of Fact 2, and hence, of Proposition 3.2.

Since separation properties are purely topological, we obtain the immediate corollary:

**Corollary 3.3.** Every quasi-isometry \( f : \tilde{X}_1 \to \tilde{X}_2 \) naturally induces a bijective correspondance between \( \mathcal{BG}_1 \) and \( \mathcal{BG}_2 \).

Now observe that for the universal cover \( \tilde{X} \) of a simple, thick, 2-dimensional hyperbolic \( P \)-manifold, we can naturally define an adjacency relation on the set \( \mathcal{BG} \). We say that a pair of elements \( \gamma_1, \gamma_2 \) of \( \mathcal{BG} \) are adjacent, denoted by \( \gamma_1 \sim \gamma_2 \) provided there exists a geodesic joining a point in \( \gamma_1 \) to a point in \( \gamma_2 \), and lying entirely within a single chamber. Note that the above relation is symmetric, but not transitive. The next step is to establish that a quasi-isometry preserves the adjacency relation.

**Proposition 3.3.** If \( f : \tilde{X}_1 \to \tilde{X}_2 \) is a quasi-isometry, then for any pair \( \gamma_1, \gamma_2 \in \mathcal{BG}_1 \), we have:

\[
\gamma_1 \sim \gamma_2 \iff f_* (\gamma_1) \sim f_* (\gamma_2),
\]

where \( f_* (\gamma) \) in \( \mathcal{BG}_2 \) is the branching geodesic bijectively associated with \( \gamma \in \mathcal{BG}_1 \).

**Proof.** This follows immediately from Proposition 3.2. Indeed, from the definition of the relation \( \sim \), we see that \( \gamma_1 \sim \gamma_2 \) if and only if the geodesics form a pair of distinct boundary geodesics of a single chamber \( C \). Given a 4-tuple of distinct points
\{x_-, x_+, y_-, y_+\} \subset \partial^\infty \tilde{X}, Proposition 3.2 (parts (1) and (2)) tells us there is a pair \(\gamma_1, \gamma_2\) satisfying \(\gamma_1(\pm\infty) = x_\pm, \gamma_2(\pm\infty) = y_\pm\) if and only if we have:

- the two pairs of points \(\{x_\pm\}, \{y_\pm\}\) each separate \(\partial^\infty \tilde{X}\) into \(\geq 3\) components,
- each of the four pairs of points \(\{x_+, y_+\}, \{x_+, y_-\}, \{x_-, y_+\}, \{x_-, y_-\}\), separate \(\partial^\infty \tilde{X}\) into precisely two components.

Since the quasi-isometry \(f\) induces a homeomorphism \(f_\infty\) between the two boundaries at infinity \(\partial^\infty \tilde{X}_1\) and \(\partial^\infty \tilde{X}_2\), the above topological characterization of endpoints of adjacent branching geodesics immediately yield the Proposition.

Next observe that the adjacency relation can be used to keep track of the chambers. This is the content of the following:

**Lemma 3.6.** Elements of \(\mathcal{C}\) correspond bijectively to maximal subsets of \(\mathcal{BG}\) on which the adjacency relation is transitive.

**Proof.** Let \(C \in \mathcal{C}\) be a chamber, and associate to it the collection of \(\gamma \in \mathcal{BG}\) which arise as the boundary components of \(C\); denote this set by \(B_C\). It is immediate from the definition of the relation \(\sim\) that the adjacency relation is transitive on \(B_C\).

Conversely, let \(B \subset \mathcal{BG}\) be a subset on which the adjacency relation is transitive. We claim that there is a \(C \in \mathcal{C}\) satisfying \(B \subset B_C\). To see this, pick \(\gamma_1, \gamma_2, \gamma_3 \in B\), and observe that the condition \(\gamma_1 \sim \gamma_2\) implies that the two branching geodesics are boundary components of a fixed chamber \(C_{12}\). Similarly, \(\gamma_2 \sim \gamma_3\) implies that they are both boundary components of a chamber \(C_{23}\). Now note that if \(C_{12} \neq C_{23}\), then they form two distinct chambers both incident to \(\gamma_2\). From Lemma 3.2, this forces \(\gamma_1\) and \(\gamma_3\) to lie in distinct connected components of \(\tilde{X} - \gamma_2\). Hence, if \(\eta\) is an arbitrary geodesic segment joining a point on \(\gamma_1\) to a point on \(\gamma_3\), we have that \(\eta \cap \gamma_2 \neq \emptyset\). Since \(\eta\) is assumed to be geodesic, by restricting we can view \(\eta\) as a concatenation of a geodesic joining a point in \(\gamma_1\) to a point in \(\gamma_2\), together with a geodesic joining a point in \(\gamma_2\) to a point in \(\gamma_3\). Since \(\gamma_1, \gamma_2\) are distinct boundary components of \(C_{12}\), the first geodesic segment must intersect the interior of \(C_{12}\) non-trivially. Likewise, the second geodesic segment must intersect the interior of \(C_{23}\) non-trivially. But this contradicts the assumption that \(\gamma_1 \sim \gamma_3\).

Since the adjacency relation is transitive on the subsets \(B_C\), and since every subset on which the adjacency relation is transitive is contained in one of the \(B_C\), we conclude that the latter are precisely the maximal subsets on which \(\sim\) is transitive, concluding the proof of the Lemma.

By combining the previous Lemma with the previous proposition, we immediately obtain the:
Corollary 3.4. If \( f: \tilde{X}_1 \to \tilde{X}_2 \) is a quasi-isometry, then \( f \) induces a bijection \( f_* \) from \( C_1 \) to \( C_2 \). Furthermore, if \( \gamma \in BG_1, C \in C_1 \) satisfy \( \gamma \subset C \), then \( f_*(\gamma) \subset f_*(C) \).

We now know that a quasi-isometry between the universal covers of a pair of simple, thick, 2-dimensional hyperbolic \( P \)-manifolds induces a bijection between the lifts of chambers. Now recall that in the situation we are interested in, the quasi-isometry \( \bar{\phi}_\infty \) from \( \tilde{X}_1 \) to \( \tilde{X}_2 \) has the additional property that it is \( (\Gamma_1, \Gamma_2) \)-equivariant. In particular, each lift of a chamber \( C \in C_i \) has a stabilizer under the action of \( \Gamma_i \) on \( \tilde{X}_i \).

Our next step is to identify the stabilizers of the various \( C \in C_i \) from the boundary at infinity. This is made precise in the following:

**Proposition 3.4.** Consider the natural action of \( \Gamma \) on \( \tilde{X} \) (where \( \Gamma = \pi_1(\tilde{X}) \)), and the corresponding induced action on \( \partial^\infty \tilde{X} \). Then for every \( C \in C \) we have that the stabilizer of \( C \) under the \( \pi_1(C) \)-action on \( \tilde{X} \) coincides with the stabilizer of \( \partial^\infty C \) under the induced \( \pi_1(C) \)-action on \( \partial^\infty \tilde{X} \).

The argument for this Proposition can be found in [5] (see the Assertion on pg. 212). Since an abstract isomorphism between \( \Gamma_1 \) and \( \Gamma_2 \) yields a \( (\Gamma_1, \Gamma_2) \)-equivariant homeomorphism between \( \partial^\infty \tilde{X}_1 \) and \( \partial^\infty \tilde{X}_2 \), this immediately yields the:

**Corollary 3.5.** The bijection \( \bar{\phi}_*: C_1 \to C_2 \) induced by the isomorphism \( \phi \) has the property that, for every \( C \in C_1 \), one has \( \text{Stab}_{\Gamma_1}(C) \cong \text{Stab}_{\Gamma_2}(\bar{\phi}_*(C)) \).

Armed with this information, it is now easy to complete the proof of the topological rigidity Theorem 1.2. We first note that, by the \( (\Gamma_1, \Gamma_2) \)-equivariance of the homeomorphism from \( \partial^\infty \tilde{X}_1 \) to \( \partial^\infty \tilde{X}_2 \), and in view of Proposition 3.3, we conclude that there are an equal number of orbits of branching geodesics in \( \tilde{X}_1 \) and \( \tilde{X}_2 \). Since each such orbit corresponds to precisely one circle in the branching locus of the respective \( X_i \), we conclude that there is a bijective correspondance between the components of the branching locus of \( X_1 \) and \( X_2 \).

Now given any chamber in \( X_1 \), one can consider the family of connected lifts of the chamber. These form a single orbit under the \( \Gamma_1 \)-action on \( C_1 \). Each lift in this orbit, by Corollary 3.4 maps to the lift of a corresponding chamber in \( C_2 \). But \( (\Gamma_1, \Gamma_2) \)-equivariance ensures that the lifts of chambers one gets in \( C_2 \) lie in a single \( \Gamma_2 \)-orbit under the corresponding \( \Gamma_2 \)-action on \( C_2 \). Finally, Corollary 3.5 implies that the original chamber in \( X_1 \), and the corresponding chamber in \( X_2 \) have the same fundamental group.

Next we note that both the number of boundary components the chamber has can be entirely determined by the number of distinct orbits of of points \( \{\gamma(\pm \infty)\} \) lying in \( \partial^\infty C \), where \( C \in C_i \) is a lift of the chamber. Again, by \( (\Gamma_1, \Gamma_2) \)-equivariance of
the homeomorphism, we obtain that pairs of corresponding chambers in $X_1$ and $X_2$ have exactly the same number of boundary components. Now observe that a surface with boundary is uniquely determined by its fundamental group and the number of boundary components it has. This tells us that the correspondence between chambers in $X_1$ and $X_2$ preserves the homeomorphism type of the chambers. To conclude, we note that the dynamics on the boundaries at infinity also allow us to keep track of how each chamber is attached to the branching strata. Putting all this together, we obtain a homeomorphism from $X_1$ to $X_2$. It is immediate by construction that this homeomorphism induces the original isomorphism on the level of the fundamental groups, completing the proof of Theorem 1.2.

4 Concluding remarks.

Our main theorem states that, within a certain class of diagrams of groups, each group that appears as a direct limit has a unique representative. An interesting question is the following:

**Question:** Which classes of diagrams of groups have the property that any group that occurs as a direct limit arises as the limit of a unique diagram?

Forester [3] has given criteria under which a Bass-Serre splitting of a group is unique (see also Guirardel [4]). We note that the Bass-Serre trees naturally associated to geometric amalgamations of free groups do not satisfy the hypotheses in Forester’s work.

Another interesting aspect of the groups we are considering lies in the fact that these groups are essentially combinatorially determined. Indeed, in order to recognize the isomorphism type of these groups, it is sufficient (by the main theorem) to keep track of:

- the ranks of the free groups arising as fundamental groups of chambers,
- the number of boundary components of each chamber
- how the chambers get glued

Since this information consists of a finite amount of data, these groups form a class of $\delta$-hyperbolic groups (or $CAT(-1)$ groups) for which one can look at various decision type problems. We can ask:

**Question:** When are the direct limits of a pair of geometric amalgamations of free groups quasi-isometric? When are they bi-Lipschitz equivalent?
