The transversus abdominis plane (TAP) block was first introduced by Rafi [1] in 2001 as an abdominal field block. The TAP block is performed by inserting a needle between the internal oblique muscle and the transversus abdominis muscle and injecting a local anesthetic solution. The TAP block has become multimodal postoperative analgesia for various abdominal surgeries [2,4,5]. However, only a few case reports have documented the use of a TAP block alone as a surgical anesthesia, and the anesthetic role of TAP blocks has not yet been clearly defined [3]. According to such case reports, TAP blocks have been adopted as the sole anesthetic technique for high-risk patients who are elderly, have severe systemic diseases, or have contraindications for other methods of anesthesia [2,4,5]. This case report differs from the previous case reports in that the TAP block was performed on a nursing primipara woman who refused other anesthesia techniques. In addition, this is the first case report in Korea of surgery using a TAP block as the sole anesthetic technique.

**CASE REPORT**

The present case report was approved by the Institutional Review Board of our hospital (no. GNAH 2019-10-003). A 33-year-old female (82.1 kg, 158.1 cm) was admitted to the hospital with abdominal pain and a mass developed after a...
Cesarean section. Seventeen days earlier, she received a lower segment transverse Cesarean section under spinal anesthesia at a gestational age of 38 + 2 weeks with polyhydramnios. An epidural catheter for patient-controlled analgesia (PCA) was placed at L4-5. During the operation, there was no anesthetic or operative complications. After the surgery, a lower rectus abdominis muscle hematoma sized 160.3 × 77.4 × 91.7 mm (Fig. 1) was found by abdominal computed tomography, and evacuation of the hematoma was planned.

The patient had no history of severe systemic disease or anticoagulant medication. In the preoperative examination, the complete blood cell count revealed a white blood cell of 11,600 /mm³ with an elevated C-reactive protein (7.48 mg/dl) and fever (38.5°C). The results of other laboratory and imaging studies, such as electrolytes, blood coagulation tests, chest X-ray, and electrocardiogram (ECG) were all unremarkable.

Prior to the surgery, the patient worried about the accumulation of an anesthetic agent in her breast milk and complained about an unpleasant personal experience with previous spinal anesthesia with epidural catheter insertion. Thus, she refused to receive any neuraxial or general anesthesia. Because of the patient’s concern, the surgical team was consulted regarding adequate anesthetic methods. The authors suggested an ultrasound (US)-guided bilateral TAP block and asked the patient for consent and cooperation.

The patient arrived in the operating room and was identified. She was provided with a blood pressure (BP) cuff to monitor her BP and was connected to an ECG machine and pulse oximetry. She was given 2 L/min of O₂ via nasal prongs throughout the operation. Her initial BP was 114/74 mmHg, pulse rate was 85 /min, and O₂ saturation was 100%.

The patient was in the supine position to perform the bilateral TAP block. Before performing the TAP block, the abdominal skin between the iliac crest and the lower costal margin at the mid-axillary line was prepared using betadine and was covered with sterile drapes. The ultrasound probe and cable were covered with a sterile plastic cover. The linear transducer (STERRAD® UST-5413 [5–10 MHz], Hitachi Aloka Medical, Japan) of the ultrasound (Prosound SSD-3500SV, Aloka Co., Japan) was placed on the right mid-axillary line between the subcostal margin and the iliac crest (Fig. 2). With an in-plane approach, the position of the external oblique muscle, internal oblique muscle, and the transverse abdominis muscle were spontaneously checked. A 23-gauge, 60 mm quincke-type needle (Kovax-needle®, Korea Vaccine Co., Korea) was inserted in the fascia layer between the internal oblique muscle and the transverse abdominis muscle to inject 10 ml of 2% lidocaine (Fig. 3). In the same manner, 10 ml of 2% lidocaine was injected into the left TAP. The operation proceeded after confirming sensory changes in the T10-T12 dermatomes using the pinprick method 10 min after the TAP block. A 5cm-sized horizontal incision was made on the scar of the previous Cesarean section, which was at the T12 dermatome. After opening the rectus abdominis fascia, 700 ml of subfascial hematoma was evacuated. The duration of operation was 30 min and the patient’s condition stabilized during the surgery.

After the operation, the patient was moved to the post-anesthesia care unit and moved to the ward after 30 min without any complaints of surgical pain. The numerical rating scale for pain at the surgical site was assessed for

![Fig. 1. Lower rectus abdominis muscle hematoma 160.3 × 77.4 × 91.7 mm in size was detected by abdominal computed tomography. It developed after a lower transverse Cesarean section which was performed 17 days ago. (A) Transverse plane image. (B) Coronal plane image.](www.anesth-pain-med.org)
two hours (one hour post-operation, 3 points; two hours post-operation, 5 points) at the ward. The patient showed normal secretion of breast milk and thus, breastfeeding was performed successfully using a breast pump.

**DISCUSSION**

Cesarean section is an essential technique for obstetrics, but there are various risks ranging from surgical site problems to life-threatening complications. Wound hematoma is one of the common complications of Cesarean sections. The incidence of wound hematoma in elective Cesarean sections was reported to be 1.3% and the odds ratio was 5.1 compared to vaginal delivery [6]. The risk factors of rectus muscle hematomas are trauma, surgery, anticoagulation therapy, pregnancy, intense contraction of the rectus muscle, and underlying diseases (hypertension, vasculitis, hematologic disease, and others) [7]. The patient in the present case had no hematologic disease and had never received anticoagulation therapy. However, it is presumed that hematoma could occur due to elevated intra-abdominal pressure by pregnancy and direct/indirect injury of the epigastric vessels during surgery.

Most of the previously published studies introduced TAP blocks only as postoperative analgesic methods. Over the years, the TAP block has proven its analgesic effect in various abdominal surgeries [2,8]. TAP blocks can reduce postoperative pain and the need for postoperative opioids for up to 48 h following abdominal procedures [8,9]. It can be used in combination with PCA or other pain medications, and can also be used as a salvage therapy when other pain medications fail [8]. However, only a few cases of the use of a TAP block as the sole anesthetic technique have been reported. Recently, TAP blocks have been used as the sole anesthetic technique in inguinal hernia repair [5,10], open gastrostomy [3], colectomy [4], ileostomy [4], wedge resection of cecal cancer [4], and abdominal wall abscess incision and drainage [11]. In particular, the last abdominal surgery mentioned above was similar to the present study in the type of surgery and location of the lesion.

Although there are some differences in the literature, the analgesic effect of TAP blocks is generally found in the T6-L1 dermatomes of the anterolateral abdominal wall [1,5,8,12]. However, a cadaveric study by Tran et al. [13] demonstrated that TAP blocks most effectively blocked the dermatomes of T11-L1 and only 50% of the T10. In addition, some studies reported that the L1 dermatome was not sufficiently blocked under a posterior TAP block [10]. One of the disadvantages of the TAP block is that it cannot relieve visceral pain mediated by the celiac plexus, which may cause discomfort in surgery stimulating intraperitoneal organs [2]. Although abdominal visceral pain could be controlled by epidural anesthesia at the proper level, the insertion of an epidural catheter was not performed due to the patient’s refusal. Because the surgical field of our patient was confined to the lower rectus abdominis muscle without opening the peritoneum, the authors believed that a lateral TAP block could effectively provide sufficient anesthestia for surgery.

Compared to other anesthetic methods, a TAP block has the following advantages. It can be used as a postoperative technique.
analgesic method [5,10]. It reduces hemodynamic fluctuation and the incidence of postoperative nausea and vomiting (PONV) [5] and it contributes to early ambulation after surgery [5]. Moreover, it can be performed in places other than the operating room with or without US [11]. Lastly, even when compared to local anesthesia, TAP blocks provide better and longer pain control with less PONV incidence [3].

However, surgeons should consider the following disadvantages of a TAP block. As mentioned, it is unable to block visceral stimulation and shows an irregular dermatomal range of analgesia [10]. It may cause toxicity due to the use of large amounts of local anesthetics [10] and it takes time to achieve the full analgesic effect after a TAP block, at least 20 to 25 min [2]. Lastly, TAP blocks may provide insufficient analgesia for abdominal midline incisions [14]. Because TAP blocks have many advantages with clear disadvantages, it is necessary to select the appropriate patient and surgical methods carefully before applying a TAP block. Also, it is important to establish adequate communication with surgeons and the patient before surgery.

The patient was a breastfeeding primipara woman with a 17 day-old neonate. She was worried about the accumulation and transmission of analgesics through the breast milk to her neonate. According to a study that evaluated the delivery of bupivacaine through breast milk after a TAP block [9], neonatal toxicity is extremely unlikely to occur. Local anesthetics, including lidocaine, seem to be safe for breastfeeding women because of their short half-life, poor oral bioavailability (less than 30%), and low concentration in breast milk [15]. Most drugs commonly used in general anesthesia are considered to be safe for the breastfeeding of healthy infants when administered in a single dose. But, in some drugs, there have been no published studies on transmission through breast milk (inhaled anesthetics, muscle relaxants, and remifentanil) or only limited data are available. If multiple administration of drugs is needed or a nursing patient has an unhealthy neonate, breastfeeding of the neonate may be adversely affected [15]. In brief, the TAP block is a safe anesthetic method for breastfeeding women, and the patient in the present case was able to proceed to breastfeeding normally from the day of the operation.

In conclusion, a breastfeeding primipara woman who rejected other anesthetic methods underwent the successful evacuation of an abdominal wall hematoma under a US-guided bilateral TAP block. A TAP block could be an effective alternative anesthetic method that may cause minimal or no visceral pain in breastfeeding females undergoing abdominal surgery.
