ABSTRACT

Objective: The prevalence of coeliac disease (CD) in Vietnam is unknown. To fill this void, we assessed the prevalence of serological markers of CD autoimmunity in a population of children in Hanoi.

Setting: The outpatient blood drawing laboratory of the largest paediatric hospital in North Vietnam was used for the study, which was part of an international project of collaboration between Italy and Vietnam.

Participants: Children having blood drawn for any reason were included. Exclusion criteria were age younger than 2 years, acquired or congenital immune deficiency and inadequate sample. A total of 1961 children (96%) were enrolled (838 females, 1123 males, median age 5.3 years).

Outcomes: Primary outcome was the prevalence of positive autoimmunity to both IgA antitransglutaminase antibodies (anti-tTG) and antiendomysial antibodies (EMA). Secondary outcome was the prevalence of CD predisposing human leucocyte antigens (HLA) (HLA DQ2/8) in the positive children and in a random group of samples negative for IgA anti-tTG.

Results: The IgA anti-tTG test was positive in 21/1961 (1%; 95% CI 0.61% to 1.53%); however, EMA antibodies were negative in all. HLA DQ2/8 was present in 7/21 (33%; 95% CI 14.5% to 56.9%) of the anti-tTG-positive children and in 72/275 (26%; 95% CI 21% to 32%) of those who were negative.

Conclusions: Coeliac autoimmunity is rare in Vietnam, although prevalence of HLA DQ2/8 is similar to that of other countries. We hypothesise that the scarce exposure to gluten could be responsible for these findings.

INTRODUCTION

Coeliac disease (CD) is a chronic small-intestinal immune-mediated enteropathy precipitated by exposure to dietary gluten in genetically predisposed individuals bearing the second class human leucocyte antigen (HLA) DQ2/DQ8 haplotypes.1 CD is characterised by the presence of a variable combination of clinical manifestations including intestinal and extraintestinal symptoms such as diarrhoea, abdominal pain, failure to thrive and anaemia. CD-specific antibodies comprise antitransglutaminase antibodies (anti-tTG), antiendomysial antibodies (EMA) and antibodies against deamidated forms of gliadin peptides.2 The sensitivity of anti-tTG and EMA is about 93%, whereas specificity has been reported to be 97% for anti-tTG and 99% for EMA.

The prevalence of CD reported in Europe and the USA averages 1% in children and adults.3–5 A few studies have been performed on symptomatic individuals in China and India,6 but, with the exception of a screening in Malaysian adults,7 the prevalence of CD in the Asia-Pacific region and, more specifically in Vietnam, is still unknown. The World Gastroenterology Organization and the Asian Pacific Association of Gastroenterology recommend establishing the prevalence of CD across that region in order to increase
-awareness among physicians and patients. When untreated, the disease can cause permanent growth failure and poor bone development, and, according to some studies, it can facilitate the development of autoimmune disorders such as diabetes and thyroiditis, infertility, and even cancer. A twofold to threefold excess in all-cause mortality among patients with untreated CD, compared with the general population, has been reported.

While wheat is the staple cereal of most Caucasian populations, the diet of many populations in Asia and South-East Asia is based on rice. Wheat-based products, however, are becoming more common with urbanisation and rising incomes in areas of Asia that were once considered traditional rice-eating regions. Changes in infant feeding patterns in Asian countries might increase the prevalence of CD. We hypothesised that eating mainly rice would protect one from developing coeliac autoimmunity.

In order to establish the prevalence of CD in the Vietnamese paediatric population, we tested a large number of children, using the serum anti-tTG as a screening test. The children who tested positive for anti-tTG were evaluated with the EMA test and for the CD-related HLA. A randomly selected group of children who had tested negative for anti-tTG and EMA were typed for CD-related HLA.

MATERIALS AND METHODS

Study design
The study was designed by the University of Ferrara, Italy, in collaboration with the National Hospital of Paediatrics (NHP) in Hanoi, Vietnam, which are partners in an international project of the University of Ferrara. In addition, the Institute for Clinical Research of the University of Trieste, Italy, participated in the research project and performed all the laboratory tests. The sample size was calculated on an estimation of 0.75% prevalence of CD. Considering a 99% CI and a precision of 0.5%, the estimated sample size was 1976. We added 5% to the sample size to compensate for any attrition.

The NHP is the second largest paediatric hospital in Southeast Asia and the second largest facility of children allowed us to enrol the necessary number in a short period of time. The children, aged 2–18 years, who presented to the laboratory of the NHP to have blood drawn for any reason between February 2 and 14, 2015, were included in the study. Exclusion criteria were: age younger than 2 years, a diagnosis of malignancy and chemotherapy treatment or treatment with immunosuppressants, including corticosteroids. In fact, testing for anti-tTG and EMA in children below 2 years of age results in poor sensitivity, and immunosuppression could also decrease the sensitivity of the tests.

Blood sampling was carried out at the NHP: two tubes were obtained from each participant, one for serum and one for whole blood. We searched for IgA anti-tTG in all the children included in the study. All the positive children were then tested for EMA and HLA DQ2/DQ8. Total IgA concentration was measured in samples with IgA anti-tTG absorbance ranging from 0 to 0.140, as previously reported, and serum samples with IgA deficiency (IgA serum concentration <7 mg/dL) were tested for IgG anti-tTG.

Furthermore, a random selection of children who tested negative for anti-tTG and EMA were also evaluated for CD-related HLA. According to the ESPGHAN criteria, a participant is defined as being at risk for having CD when positive for anti-tTG and EMA in the presence of HLA DQ2/DQ8.

A questionnaire was used to collect demographic data (sex, date of birth, current therapies), information on signs and symptoms known to be related to CD (recent symptoms of abdominal discomfort or fatigue), and on the approximate amount of gluten consumed weekly (noodles, bread or snacks: never, once a day, more or less than once a week).

Serological assays and HLA typing
Serum samples were examined in duplicate at the NHP laboratory for IgA anti-tTG, using an ELISA assay (Eu-tTG, Eurospital, Trieste, Italy) according to the manufacturer’s instructions (normal values <9 U/mL). Quantitative determination of human IgA in serum was carried out in Italy using an immunoassay (Roche/Hitachi Cobas c system, Indianapolis, Indiana, USA), following the manufacturer’s instructions. Serum EMA were evaluated by indirect immunofluorescence on cryostat sections of human umbilical cord, as previously described.

The susceptibility alleles for CD were determined by PCR with allele-specific primers identifying HLA DQ2 and DQ8, using an Eu-Gene-Risk kit (Eurospital, Trieste, Italy). The kit serves to identify all DQ2-positive participants carrying both DQ2.5 (HLA-DQA1*05, DQB1*02 in cis with DR5 or in trans with the DR5/DR7 haplotypes) and DQ2.2 heterodimers (HLA-DQA1*01, DQB1*02, DRB1*07), and those positive for DQ8 (HLA-DQA1*03, DQB1*03:02, DRB1*04).

Statistical analysis
Continuous data were presented as mean±SD for normally distributed parameters, and median and IQR for skewed variables. Dichotomous variables were presented as frequency and percentage.

Ethical considerations
Written informed consent was obtained from the children’s parents before proceeding with the tests.

RESULTS

Study population
The parents of 2045 children agreed to participate in the study. Eighty-four children (4%) were excluded due to inadequate serum samples (63 children) or to...
exclusion criteria (15 with leukaemia, 3 in chemotherapy, 1 in radiotherapy, 2 under 2 years of age). Nineteen hundred and sixty-one children (96%) were enrolled in the study (838 females, 1123 males, median age 5.3 years and IQR 4–7.5 years). Reasons for having blood drawn included an array of general paediatric diseases: respiratory tract infections, fever, gastroenteritis, cough, hepatitis, thalassaemia major, anaemia, abdominal pain, nephrotic syndrome, glomerulonephritis, stunted growth, thyroiditis, diabetes, arthritis, asthma, tuberculosis, urinary tract infection, dengue, Henoch-Schonlein purpura and immune thrombocytopenia.

Twenty per cent of the children (387/1961) presented with gastrointestinal symptoms (266 of recurrent abdominal pain, 87 anorexia, 58 diarrhoea). One hundred and twenty-eight others were being worked up because of failure to thrive. Exposure to gluten was reported by 88% of the patients’ parents. Four per cent of them ate foods containing gluten every day, 40% at least once a week and 56% less than once a week.

**Anti-tTG, EMA and HLA typing**

Twenty-one children out of 1961 (8 females, 13 males) tested positive for IgA anti-tTG (1%; 95% CI 0.61% to 1.53%) and 17 of the 21 had a history of eating gluten. However, EMA antibodies were negative in all of them. Seven of the 21 (33%) carried the CD-related HLA (table 1), but only in 2 (0.1% of the total population) was the titre of anti-tTG antibodies higher than three times the upper limit of normal (positive predictive value 95%). One patient had an IgA anti-tTG titre 10 times higher than the upper limit of normal values but his HLA DQ2/8 was negative. HLA DQ2/8 was present in 7/21 (33%; 95% CI 14.5% to 56.9%) of the anti-tTG-positive children. The HLA DQ2/8 was measured also in 275/1961 (14%) children (selected by means of a computational random number generator) who had tested negative for anti-tTG and EMA, and 72/275 (26%; 95% CI 21% to 32%) demonstrated presence of the HLA DQ2/8.

IgA anti-tTG absorbance ranging from 0 to 0.140 was present in 162/1961 children (8%) and 5/162 (3%: 3 females, 2 males, median age 6.4 years) had total IgA deficiency. These five children were tested and were found to be negative for IgG anti-tTG. The results of the study are shown in figure 1.

**DISCUSSION**

This is the first study on the prevalence of coeliac-specific antibodies among Vietnamese children. CD is considered to be rare in the Asia-Pacific region. Therefore, we screened a large sample of children who had not previously been diagnosed with CD, by means of sensitive and specific sequential serological tests. Overall, 21 children were found to be anti-tTG IgA positive, but the EMA test was negative in all, and only 7/21 were positive for CD-related HLA. Only two children were potentially affected by CD, having high levels of anti-tTG and being DQ2/DQ8 positive. However, both

*IgA anti-tTG titre was 10 times higher than the upper limit of normal values but HLA DQ2/8 was negative.

Anti-tTG, antitransglutaminase antibodies; EMA, antientomysial antibodies; F, female; HLA N, HLA DQ2/8 negative; M, male.
were EMA negative. According to the literature and the recent ESPGHAN and BSPGHAN guidelines for CD diagnosis, the EMA test is considered a gold standard immunological biomarker as sensitive as, but more specific than, anti-tTG, the increase of which might be caused also by parasitosis. The remainder of the children who tested positive for DQ2 and DQ8 were anti-tTG and EMA negative.

All the screening studies performed so far in the Eastern Hemisphere have identified the presence of CD autoimmunity in variable percentages. In India, CD has been well recognised, especially in the north, and two population-based studies revealed a prevalence of 0.3 to 1.04%. According to a meta-analysis, the number of reported cases of CD is extremely low in China, although a study of children with chronic diarrhoea showed a histologically proven frequency of CD equaling 12%. Preliminary data from Japan and Singapore suggest the existence of CD also in these countries. A study from Malaysia reported a prevalence of 1.9% in adult females and 0.4% in males as demonstrated by positive IgA/IgG antigliadin antibodies, IgA/IgG anti-tTG and EMA.

The pathogenesis of CD is linked to involvement of the HLA molecules, DQ2 or DQ8, which present gluten antigens to specific T-cells. Their presence is a condition not sufficient but necessary condition to develop CD. The typical HLA alleles were present in 26% of the Hanoi children examined, a number similar to the percentages found in most populations. The low prevalence of CD autoimmunity in our northern Vietnamese paediatric population is therefore somewhat surprising, especially in consideration of the fact that HLA genotyping suggests that the risk for CD exists also in Vietnam.

Possible explanations for this finding could be the young median age of the children screened (5.3 years) or the scarce and late introduction of gluten. A recent multicentre, prospective European study demonstrated that, although late introduction of gluten did not decrease the risk of developing CD in children with predisposing conditions, it delayed the onset of the disease. Approximately half of the Vietnamese children that we examined ate gluten-containing foods less than once a week, and 10% did not eat gluten at all. This fact could be responsible for the rarity of coeliac autoimmunity.

IgA deficiency occurs more frequently in patients with CD (1.30%) than in the general population (0.13 to 0.25%), a fact that might cause false-negative results. In our study, the children who were considered as being partially affected by total or partial IgA deficiency on the basis of low IgA anti-tTG absorbance were tested with IgG anti-tTG and found to be negative.

In our population, there was a prevalence of males. This difference reflects the male-to-female ratio, which averages 120:100 (45% female) in the Red River Delta (Hanoi City) and 110:100 (47% female) in the rest of the northern areas.

Our results are similar to those recently reported from Colombia, where healthy individuals and those affected by autoimmune disorders were both tested with anti-tTG and EMA. Among patients with autoimmune disorders, seven individuals tested positive or weakly positive for anti-tTG, but IgA EMA were negative in all cases.
Strengths and limitations of the study
The strength of our study lies in the fact that this is the first research on CD autoimmunity in Vietnam; in the large number of children examined by ELISA for anti-tTG; in the further testing by EMA of positive sera, and in the HLA typing for DQ2 and DQ8 of the anti-tTG-positive children. Also, in children affected by total or partial IgA deficiency, anti-tTG IgG were measured. The amount of gluten introduced with food was estimated by means of a detailed questionnaire with the best possible accuracy.

The study was performed on children having blood drawn as outpatients at a hospital laboratory, who therefore were not completely healthy. However, if anything, this potential selection bias should have increased the prevalence of CD in our sample. The median age of children was 5 years, and we do not know if CD autoimmunity will develop with passing years. A small-intestinal biopsy could not possibly be performed and therefore the presence of histological lesions in the two patients (V170, V148) with high anti-tTG antibody concentration carrying the CD-related HLA cannot be completely excluded. Both had been exposed to dietary gluten.

Future developments
New studies on the Southeast Asian population might clarify whether the prevalence of CD increases with age and if there is a strict correlation with the amount of gluten introduced with the diet. It will be of interest to follow children on a completely gluten-free diet and compare them with children from the same area whose diet includes gluten-containing foods.

CONCLUSIONS
None of the 1961 Vietnamese children examined were positive for coeliac autoimmunity on the basis of positivity for anti-tTG and EMA. The extremely low prevalence of CD in this large population of children could be due to low exposure to gluten coupled with the young age of the children.

Acknowledgements
The authors thank the nurses at the NHP of Hanoi without whose help this study would not have been possible, and the parents of the children, who patiently answered many questions. They also acknowledge the secretarial help of Ms Cinzia Toniolli.
