1 INTRODUCTION

The fastest stars travel so rapidly that they can escape from the Milky Way’s gravitational well. These ‘hypervelocity stars’ (Hills 1988, Brown et al. 2005, Brown 2015) are objects of ongoing study because their origin in the tidal disruption of binaries by massive black holes, chaotic N-body stellar encounters, or the supernova of their companion star makes them invaluable probes of these events. Only a few tens of hypervelocity stars are known1 and thus we are still in the regime where individual hypervelocity star discoveries are noteworthy.

The Gaia space telescope (Gaia Collaboration 2016) is expected to enable the discovery of hundreds of hypervelocity stars (Marchetti et al. 2018b), because it will make the first measurements of the tangential velocities of over a billion stars and the radial velocities of over 100 million. The diverse data produced by Gaia have necessitated separate pipelines for the astrometry, Radial Velocity Spectrometer (RVS), and colour photometry (GBP and G_BP), and each of these complicated pipelines was still in active development at the time of the preliminary second Gaia data release (DR2; Gaia Collaboration 2018), which limited the number of stars published with these measurements. None the less, Marchetti et al. (2018b) predicted that among the limited sample of 7 224 631 stars with radial velocities in DR2 there would be a handful of hypervelocity stars.

The Gaia DR2 RVS sample was a crowded hunting ground with Marchetti, Rossi & Brown (2018a), Hattori et al. (2018), and Bromley et al. (2018) all conducting searches for high-velocity stars:

(i) Marchetti et al. (2018a) identified as many as 20 stars with a probability greater than 80 per cent of being unbound from the Milky Way. Surprisingly, only 7 of these stars were consistent with originating in the Milky Way disc and thus Marchetti et al. (2018a) proposed an extragalactic origin for the remaining 13 stars.
(ii) Hattori et al. (2018) reported 30 stars with extreme space velocities (greater than 480 km s\(^{-1}\)). They conjectured that one or two could originate in the Galactic Centre, as many as three might originate in the Large Magellanic Cloud, and that the

ABSTRACT

Gaia DR2 5932173855446728064 was recently proposed to be unbound from the Milky Way based on the \(-614.3 \pm 2.5\) km s\(^{-1}\) median radial velocity given in Gaia DR2. We obtained eight epochs of spectroscopic follow-up and find a very different median radial velocity of \(-56.5 \pm 5.3\) km s\(^{-1}\). If this difference were to be explained by binarity, then the unseen companion would be an intermediate-mass black hole; we therefore argue that the Gaia DR2 radial velocity must be in error. We find it likely that the spectra obtained by Gaia were dominated by the light from a star 4.3 arcsec away, and that, due to the slitless, time delay integration nature of Gaia spectroscopy, this angular offset corresponded to a spurious 620 km s\(^{-1}\) shift in the calcium triplet of the second star. We argue that such unanticipated alignments between stars may account for 105 of the 202 stars with radial velocities faster than 500 km s\(^{-1}\) in Gaia DR2 and propose a quality cut to exclude stars that are susceptible. We propose further cuts to remove stars where the colour photometry is suspect and stars where the radial velocity measurement is based on fewer than four transits, and thus produce an unprecedentedly clean selection of Gaia radial velocities for use in studies of Galactic dynamics.

Key words: binaries: general – stars: kinematics and dynamics.
et al. (2018a) found 2197 Sun. The known main-sequence hypervelocity stars have a mean heliocentric distance of more than 50 kpc (Boubert et al. 2018) and thus a hypervelocity star as close as 2 kpc would probe a new kinematic regime and allow the first detailed characterization of a hypervelocity star’s motion, atmosphere, and chemistry. Bromley et al. (2018) sounded a note of caution because Gaia DR2 593...064 was the only one of their 25 candidates that was flagged as a DUPLICATED_SOURCE (likely due to it being in a crowded field) and suggested that follow-up observations would be necessary.

The objective of this work is to conduct follow-up of Gaia DR2 593...064 to ascertain whether it is a genuine hypervelocity star. In Section 2, we highlight the unusual concentration of other stars around Gaia DR2 593...064 in SkyMapper images and present eight new epochs of ground-based spectroscopic radial velocities that are in tension with the Gaia radial velocity. We argue in Section 3 that the inconsistency can only be reconciled if either Gaia DR2 593...064 is in orbit around an intermediate-mass black hole (IMBH) or the Gaia measurement is spurious, and conclude the latter to be much more likely. In the remainder of Section 3, we identify a novel failure mode in the Gaia RVS pipeline and discuss the implications of this for the use of Gaia radial velocities.

2 OBSERVATIONS

2.1 Images and photometry

Gaia DR2 593...064 lies close to the plane of the Milky Way at (l, b) = (329.9°, −2.7°), which led Bromley et al. (2018) to conjecture that the Gaia data may suffer from it being in a crowded field. In the Gaia catalogue, there are 18 other sources within a 20 × 20 arcsec cut-out centred on Gaia DR2 593...064. To illustrate the density of these sources, we show 20 arcsec and 100 arcsec images from SkyMapper DR1 (Wolf et al. 2018) in Fig. 1. We queried the 2MASS point source catalogue (Skrutskie et al. 2006), SkyMapper DR1.1, and the GLIMPSE Source Catalog (contains photometry from the IRAC instrument on Spitzer; Benjamin et al. 2003; Churchwell et al. 2009); 2MASS contains four sources in this field (excluding Gaia DR2 593...064), SkyMapper also contains four sources (including Gaia DR2 593...064), whilst GLIMPSE contains five sources (including Gaia DR2 593...064). The final list of photometry of Gaia DR2 593...064 is given in Table 1.

We quantified whether this density of neighbours is unusual by querying in the full Gaia DR2 catalogue for neighbours within 8 arcsec of the 34 Gaia DR2 RVS stars with radial velocity greater than 500 km s⁻¹ that meet the quality criteria of Marchetti et al. (2018a). Gaia DR2 593...064 has the most neighbours, with 9. There is one star with 7 neighbours (Gaia DR2 5926621184202272256; but none are within 4 arcsec) and the rest have 3 or fewer neighbours. We concluded that Gaia DR2 593...064 is in an abnormally crowded field and thus that follow-up spectra are required to verify the Gaia radial velocity.

2.2 Spectra of Gaia DR2 593...064

We observed Gaia DR2 593...064 on eight epochs over the date range 2018 May 5 to 2018 September 16 using the Goodman Spectrograph (Clemens, Crain & Anderson 2000) on the SOAR telescope. Each spectrum was obtained with a 0.95 arcsec longslit. The first six epochs used a 1200 lines mm⁻¹ grating, giving a wavelength coverage of 4300–5585 Å with a resolution of 1.7 Å. The latter two epochs used a 2100 lines mm⁻¹ grating that gave

remaining stars were likely halo objects based on their old age. Hattori et al. (2018) noted that this implies the escape velocity near the Sun must be around 600 km s⁻¹.

(iii) Bromley et al. (2018) whittled the Gaia DR2 RVS sample down to just 25 likely high-velocity stars and singled out two as being likely hypervelocity stars, while the other high-velocity stars were categorized as statistical outliers. Of their two likely candidates, Bromley et al. (2018) cautioned that Gaia DR2 1383279090527227264 is possibly a bound late-type giant and that Gaia DR2 5932173855446728064 would require follow-up observations because it lies in a crowded field.

There are many potential pitfalls when identifying hypervelocity stars in Gaia DR2, because calculation of the total Galactocentric velocity relies on estimating a distance from the parallax. There are known issues with the Gaia DR2 parallaxes, such as a systematic offset that varies as a function of position and magnitude and the need to add a systematic component to the published uncertainties. If these issues are not accounted for then the distance may be overestimated, which propagates into an inflated Galactocentric velocity and a false positive hypervelocity candidate. One example of this is given in appendix D of Marchetti et al. (2018a), where the authors show that including the approximate global parallax offset of −0.029 mas results in only 4 out of 20 of their candidates still having a probability greater than 80 per cent of being unbound. Similarly in appendix E, Marchetti et al. (2018a) show that appropriately inflating the uncertainties in the parallax (without including the parallax offset) causes only 5 out of 20 of their candidates to still be likely unbound. Undoubtedly, the uncertainties and systematics will be better understood with the later Gaia data releases. Until then, it remains true that the only guaranteed hypervelocity stars are those in which the radial velocity alone is greater than the escape velocity.

Fortuitously, there is one such star among the crop of candidates found by these three searches: Gaia DR2 5932173855446728064 (hereafter referred to as Gaia DR2 593...064). This star has an incredible radial velocity of −614.286 ± 2.492 km s⁻¹, which alone is sufficient to class it as a hypervelocity star. This object was the premier candidate of both Marchetti et al. (2018a) and Bromley et al. (2018). It was absent from the candidate list of Hattori et al. (2018) due to their choice to select high-tangential-velocity stars as

| 2458377.50  | −52.3 ± 3.9                 |

Our median: −56.5 ± 5.3
Gaia median: −614.3 ± 2.5
Difference: 557.8 ± 5.9

A higher resolution of 0.8 Å over a wavelength range of 4500–5160 Å or 6040–6610 Å, respectively. The exposure times ranged from 300–600 s depending on conditions. All data were reduced and optimally extracted in the usual way, and wavelength calibrated using contemporaneous FeAr arcs. Barycentric radial velocities were derived through cross-correlation with standards taken with the same set-up and these were then corrected to obtain the heliocentric velocities (see Table 2).

While Gaia DR2 reports a remarkably precise radial velocity of 614.286 ± 2.492 km s^{-1}, these two numbers are actually the median of the seven individual radial velocity measurements and the uncertainty on that median, estimated as

\[
e_{v_t} = \sqrt{\left(\frac{\pi}{2N} S(v_t)\right)^2 + 0.11^2}
\]

where \(S(v_t)\) is the standard deviation of the measurements and the 0.11 km s^{-1} is the calibration floor (Katz et al. 2019). Inverting this, we can calculate that the standard deviation of the measurements is 5.17 km s^{-1}. If we calculate the median of our eight epochs in an equivalent way (without including a calibration floor and neglecting the individual measurement uncertainties), then we find −56.5 ± 5.3 km s^{-1}. The median of our radial velocity measurements is offset by 557.8 km s^{-1} from the Gaia median and this difference must come from either the system being a binary (and thus the radial velocity measured by Gaia not being the systemic radial velocity) or the Gaia measurement being spurious. We discuss both scenarios in the following section.

To extract information on the atmospheric parameters of Gaia DR2 593...064, we use a grid of synthetic spectra computed by Allende Prieto et al. (2018) using the FERRE code (Allende Prieto et al. 2006). The grid contains models with the stellar parameters effective temperature \(T_{\text{eff}}\), surface gravity \(\log g\), and overall metallicity [Fe/H] as free parameters. The limits of the grid are −5 ≤ [Fe/H] ≤ 1 dex; 5500 ≤ \(T_{\text{eff}}\) ≤ 8000 K, and 1.0 ≤ \(\log g\) ≤ 5.0 dex. In addition, the grid is extended to account for broadening due to rotation \((v \sin i)\) in steps of 5 km s^{-1}. The microturbulence is fixed to \(\log \xi = 0.176 \text{ cm s}^{-1}\). The atmospheric parameters are determined from the Alpha (spectrum covering 6040–6610 Å), Beta (spectrum covering 4500–5160 Å), and Blue (a stack of the six spectra with lower resolution) spectra. Both the grid and the three spectra are normalized using a running mean filter with a window of 35 pixels. The FERRE code utilizes Markov chain Monte Carlo (MCMC) to identify a posterior on the atmospheric parameters,
assuming cubic interpolation of the spectra between the grid points. Ten Markov chains of 1000 burn-in steps and 4000 science steps were used in each of the three analyses. In Fig. 2, we illustrate the analysis of the Blue and Alpha SOAR spectra, which have two different gratings (1200 and 2100 lines mm\(^{-1}\)).

To aid the discussion in the remainder of this work, we combine the information from the three spectra into a joint posterior on the atmospheric parameters and stellar properties. The method described above results in three sets of MCMC samples from the posterior over the atmospheric parameters, corresponding to the Alpha, Beta, and Blue spectra. The Alpha and Blue spectra cover mutually exclusive wavelength regions and thus the inferences drawn from each spectra can be treated as independent, with the implication that the results can be combined to obtain a more precise inference of the atmospheric parameters. Note that the wavelengths covered by the Beta spectrum are a subset of the wavelengths covered by the Blue spectrum and thus we use only the Alpha and Blue spectra to obtain the final atmospheric parameters.

The standard way to combine the inferences drawn from independent data sets is to treat the posterior from applying the model to the first data set as the prior when applying the model to the second data set. We note that the two sets of posterior samples can be equivalently viewed as samples from the likelihood, because we assumed a uniform prior on the atmospheric parameters. We use kernel density estimation to construct approximate PDFs describing the two sets of samples and run a third Bayesian inference with the posterior for the Alpha spectrum as the prior and the posterior for the Blue spectrum as the likelihood. One assumption underlying this method is that the kernel density estimate of the PDFs is an accurate representation of the true PDFs, which is only likely to be true if the true PDFs are smooth and continuous (e.g. there is not a valley of low probability lying between the posteriors); the samples describing the Alpha posterior enclose the volume of the Blue posterior, suggesting that this is not the case. Samples are drawn from the posterior using the MCMC emcee (Foreman-Mackey et al. 2013) Python module using 50 walkers with 1000 burn-in steps and 4000 science steps. In Fig. 3, we show this posterior together with the prior and likelihood.

We translate the posterior on [Fe/H], \(T_{\text{eff}}\), and \(\log g\) into a posterior on the mass, age, stage, luminosity, and radius of the star using the PARSEC version 1.2S isochrones (Marigo et al. 2017), which features a lognormal initial mass function and covers the range \(6 < \log(\text{Age/yr}) < 10.1\) in steps of 0.05 dex and the range \(-2.1 < [\text{Fe/H}] < 0.5\) in steps of 0.1 dex. We construct a 3-dimensional tree of all the isochrone points as a function of [Fe/H], \(T_{\text{eff}}\), and \(\log g\) using the Maneewongvatana & Mount (1999) algorithm as implemented in Scipy. For each of the posterior samples obtained in the previous paragraph, we identify the nearest 10 isochrone points; the agglomeration of these points can be interpreted as an approximate posterior in the stellar parameters. The medians and 1\(\sigma\) intervals of the posterior are given in Table 3, while a corner plot of \(T_{\text{eff}}, \log g, [\text{M/H}]\), and \(v_{\sin i}\) is shown in Fig. A1 of Appendix A. The star is hot (\(T_{\text{eff}} = 6627^{+64}_{-56}\) K) and puffy (\(\log g = 2.94^{+0.08}_{-0.07}\)) and thus is likely to be an A star that either is on the main sequence or has recently turned off to the sub-giant branch. The star is rotating at \(v \sin i = 110 \pm 5\) km s\(^{-1}\), which is only slightly faster than the 100 km s\(^{-1}\) median rotation speed in the Royer et al. (2002) catalogue of 2151 A-type stars. This rotation rate agrees with the visually broadened lines in the higher resolution spectra.

### 2.3 Spectra of nearby stars

Motivated by the proximity of a number of comparably bright stars (see Fig. 1), we obtained single-epoch ground-based spectroscopic follow-up of two near neighbours of Gaia DR2 593...064: Gaia DR2 593217385446724352 (hereafter Gaia DR2 593...352) and Gaia DR2 5932173851032088576 (hereafter Gaia DR2 593...576). Radial velocities were derived from these spectra using cross-correlation following the same procedure described in the previous section.

Gaia DR2 593...352 is not only the brighter of the two nearby stars (\(G = 13.38\)), but it is also brighter than Gaia DR2 593...064 (\(G = 13.81\)) and thus is bright enough that it has a Gaia DR2 RVS measurement. Our radial velocity of \(0.96 \pm 0.56\) km s\(^{-1}\) is entirely consistent with the median RVS value of \(5.40 \pm 2.85\) km s\(^{-1}\) based on seven transits. Gaia DR2 593...352 is only 4.284 arcsec away from Gaia DR2 593...064 and thus it is curious that Gaia DR2 593...352 has neither a \(G_{\text{BP}}\) nor a \(G_{\text{RP}}\) reported measurement, which could be an indication that the blue and red spectra of this star were flagged as blended (Riello et al. 2018).

Gaia DR2 593...576 is a \(G = 14.4\) star only 3.234 arcsec away from Gaia DR2 593...064. It is too faint (\(G_{\text{BP}} = 13.5\)) for it to be surprising that it does not have an RVS measurement in Gaia DR2. We find a radial velocity of \(-58.62 \pm 1.41\) km s\(^{-1}\), which is consistent with our median radial velocity of Gaia DR2 593...064.

We discuss both of these stars in more detail in the following sections.

### 3 DISCUSSION

The highly significant discrepancy between the Gaia DR2 radial velocity and our ground-based measurements demands an explanation. We discuss in turn the two scenarios: (1) the Gaia measurement is genuine and the system is in a high-amplitude binary and (2) the Gaia measurement is spurious in a way that escaped the cuts applied by the Gaia Data Processing and Analysis Consortium. We then discuss the implications of our finding for the handling of Gaia DR2 RVS data in the future.

#### 3.1 Scenario 1: the Gaia measurement is genuine

If the Gaia measurement is genuine, then the most likely explanation is that Gaia DR2 593...064 is in a high-amplitude binary. In this scenario, the radial velocity measured at any given epoch is the systemic velocity of the binary added to the orbital velocity of the star within the binary, and so would vary over the orbital period of the binary. Extreme binaries can have orbital velocities of hundreds of km s\(^{-1}\) (e.g. Lu & Rucinski 1999 and the other 14 papers in that series) and thus this could potentially solve the discrepancy.

A barrier to testing this hypothesis is that the Julian date of the individual Gaia radial velocity measurements was not released in DR2. We obtain a list of predicted dates at which a star at a given location on the sky will transit across CCD rows 4–7 on the Gaia focal plane (potentially allowing a radial measurement to be made) from the online ESA Observation Forecast Tool.\(^2\) In the full mission, Gaia DR2 593...064 is predicted to transit CCD rows 4–7 75 times, with 42 of these occurring in the time period covered by Gaia DR2 (see Fig. 4). The reason that only 7 of these 42 transits resulted in a radial velocity measurement is scanning law dead time as a result.

---

\(^2\)https://gaia.esac.esa.int/gost/ accessed 06/09/2018.
Figure 2. Illustration of the analysis performed on the eight spectra obtained using the Goodman Spectrograph on the SOAR telescope. Top: the normalized stacked spectrum of Gaia DR2 593...064 covering the range 4300–5585 Å (black line) and the best fit derived by FERRE (red line), with the residuals shown at the bottom of the panel. The normalization was done using a running mean filter with a 35 pixel window. The best-fitting stellar parameters are also shown. Bottom left: same analysis applied to the normalized spectrum covering the region 6040–6610 Å. Note that the series of lines in the region 6270–6300 Å that are not well fitted by the model are likely related to the well-known diffuse interstellar band at around 6284 Å. Bottom right: We estimated the signal-to-noise ratio of the spectrum in the top panel by fitting a Gaussian to the residuals (in units of normalized flux), finding \( S/N = 74.8 \).

Figure 3. 68 per cent and 95 per cent contours of the joint posteriors over \( \log g \) and \( T_{\text{eff}} \) based on the Alpha and Blue spectra. When these distributions are treated as the prior and likelihood of a Bayesian inference, the posterior shown in green is the optimal combined inference. Note that these three distributions are marginalized over [Fe/H] for illustrative purposes.

Table 3. Posterior parameters for Gaia DR2 593...064.

| Parameter          | Posterior range |
|--------------------|-----------------|
| \( T_{\text{eff}} \) (K) | \( 6627.5^{+63.6}_{-46.3} \) |
| \( \log g \)         | \( 2.94^{+0.08}_{-0.12} \) |
| [Fe/H]              | \( -0.05^{+0.03}_{-0.04} \) |
| v sin i             | \( 110^{+5}_{-5} \) |
| Mass (M\(_{\odot}\)) | \( 2.84^{+0.26}_{-0.18} \) |
| Radius (R\(_{\odot}\)) | \( 9.42^{+1.19}_{-1.26} \) |
| Age (Myr)           | \( 437^{+76}_{-98} \) |
| Luminosity          | \( 2.19^{+0.16}_{-0.10} \) |

of ‘nominal orbital maintenance operations; inadequate resources for placement of the windows at the detection chain level in high-density regions; deletion in the on-board memory as a result of inadequate capacity, particularly when both telescopes are scanning the Galactic plane; and data transmission losses’ (Cropper et al. 2018). The dead time fraction is expected to exceed 40 per cent at the faint end.
measured the radial velocity to be 614.29 ± 5.17 km s\(^{-1}\) at each of these epochs. Combining these seven epochs with our eight epochs thus gives us a radial velocity time series of 15 points. The question then arises: What are the properties of the fiducial binary system given this data set? We apply THE JOKER (Price-Whelan et al. 2017), a custom Monte Carlo sampler for the two-body problem, and specify a prior on the orbital period of the binary that is log-uniform over the range (1, 10000) d. We otherwise use the default priors in THE JOKER: that the eccentricity follows Beta(0.867, 3.03) (Kipping 2013), that the pericentre phase and argument are uniform over \([0, 2\pi)\), and that the systemic velocity and velocity semi-amplitude are broad Gaussians that are essentially flat over the region of interest. We requested \(3 \times 10^5\) prior samples and obtained 1718 posterior samples, which we show in Fig. 5. The posterior requires that the binary orbital period must be longer than 1000 d and that the minimum mass of the unseen companion is at least \(3 \times 10^3\) M\(_\odot\) (calculated by assuming that the binary is edge-on).

\textit{Gaia} DR2 593...064 being a member of a binary system is only a tenuous explanation of the large offset between our radial velocities and \textit{Gaia}’s if the unseen companion is an IMBH. One circumstantial piece of evidence in favour of this hypothesis is that \textit{Gaia} DR2 593...064 has an unusually large number of neighbours, as shown in Fig. 1 and discussed in Section 2. Merritt, Schnittman & Komossa (2009) first proposed that massive black holes (>10^6 M\(_\odot\)) ejected from a galaxy centre by the gravitational wave recoil post-merger could host a small cluster of bound stars, which they termed a ‘hypercompact stellar system’. O’Leary & Loeb (2009) considered the analogous ejection of the central black holes (<10^5 M\(_\odot\)) of the low-mass galaxies that merged to form the Milky Way and found that there may be hundreds of such systems in the halo, typically consisting of tens to hundreds of stars. Rashkov & Madau (2014) used cosmological simulations to predict that hundreds of naked IMBHs (i.e. without an accompanying dark matter subhalo) may populate the Milky Way halo and that the IMBHs within 8 kpc would host a cusp of stars with an angular extent of 2–10 arcsec, comparable to the angular size of the group of stars shown in Fig. 1.

One argument against an IMBH interpretation is that \textit{Gaia} DR2 593...064 is young (437\pm19 Myr), while the IMBHs predicted by O’Leary & Loeb (2009) would have been brought into the Milky Way by the minor mergers of small dwarf galaxies and thus should host old stellar populations. Neither of the other two stars of which we obtained spectra exhibits extreme radial velocities (\textit{Gaia} DR2 593...352 at 1.0 ± 0.6 km s\(^{-1}\); \textit{Gaia} DR2 593...576 at −58.6 ± 1.4 km s\(^{-1}\)), although if they are farther out from the nominal black hole then we might not expect them to do so. A strong argument against the existence of the black hole is the close alignment between the radial velocity of \textit{Gaia} DR2 593...352 and the median radial velocity of \textit{Gaia} DR2 593...576 (−56.5 ± 5.3 km s\(^{-1}\)); if \textit{Gaia} DR2 593...064 is in orbit around a black hole then this velocity is not at all representative of the systemic velocity of the system, but if it is single (or in a stellar mass binary) then the alignment suggests that these two stars are co-moving. The parallax of \textit{Gaia} DR2 593...3576 suggests it is too distant (\(\sigma = 0.2053 \pm 0.0364\) mas) to be associated with \textit{Gaia} DR2 593...064 (\(\sigma = 0.4540 \pm 0.0290\) mas); however, the significance of its astrometric excess noise is 2.25, indicating that the astrometric solution may not be trustworthy.

One sanity check we performed was to calculate the preferred binary orbital solution for our eight ground-based measurements on their own. We requested \(3 \times 10^5\) prior samples and obtained 15588 posterior samples, using the same log-uniform (1, 10000) d prior on the period. The motivation for requesting 10 times more samples was that many of the posterior samples would require \textit{Gaia} DR2 593...064 to be outside of its Roche lobe. Note that whether a sample \(S\) leads to Roche lobe overflow depends on the uncertain mass and radius of \textit{Gaia} DR2 593...217 and on the unknown inclination of the binary. We accounted for this in a probabilistic way:

(i) We drew 100 random values for the mass and radius of \textit{Gaia} DR2 593...064 from the posterior samples described in Section 2 and, correspondingly, 100 random values for the inclination of the binary.

\begin{figure}
\centering
\includegraphics[width=\textwidth]{figure4.pdf}
\caption{The possible dates on which \textit{Gaia} is predicted to measure the radial velocity of \textit{Gaia} DR2 593...064 and the dates on which our eight epochs were taken. Only data taken prior to 2016 May 23 was included in \textit{Gaia} DR2 and of those 42 possible epochs, 26 lie in a ‘plateau’ where it is possible that all seven \textit{Gaia} epochs were obtained in just a few days.}
\end{figure}
(ii) We determined, for each sampled orbit $S$, the fraction $F$ of the 100 realizations where the Roche lobe radius at periastron (Eggleton 1983) was exterior to the radius of the star.

(iii) We drew a uniform variate $u$ for each of the sampled orbits $S$ and discarded that sample if $u$ was greater than $F$.

This procedure cut the number of orbit samples from 15,588 to 1,068, and thus demonstrated the importance of accounting for the Roche lobe of stars in high-velocity-amplitude binary systems. We show the orbits corresponding to these 1068 samples in Fig. 6.

There are three classes of solutions apparent in Fig. 6: 30 per cent have short periods $P < 40$ d (top panel of Fig. 6), 62 per cent of the orbits lie in a single posterior mode with period $P = 51.8 \pm 4.5$ d (middle panel), and the remainder have long periods $P > 70$ d (bottom panel). One interpretation of the long-period orbits is that Gaia DR2 593...064 is not in a binary and thus has a constant radial velocity. We tested whether the trend of positive slopes in the bottom panel of Fig. 6 is real by fitting a straight line to the eight radial velocity epochs using EMCEE; the slope of the line is greater than zero for only 92 per cent of the samples and thus we cannot reject the possibility that Gaia DR2 593...064 is single at the 5 per cent level. An argument against this star being single is that there is a strong signal of rotational broadening in the spectral lines ($v \sin i = 110 \pm 5$ km s$^{-1}$), which could be explained by the effect of tides in a close binary. An alternative interpretation of the long-period orbits is that they correspond to the IMBH solution identified above, although this would require that the rapid rotation of Gaia DR2

---

Figure 5. The binary orbital solution if all seven Gaia RVS measurements were taken during a 3.75-d period. Top: posterior radial velocity tracks with the measurements overplotted. Bottom left: posterior in period–amplitude space. Bottom right: posterior constraint on the minimum mass of the unseen companion, assuming an inclination of 90 deg.
The counter scenario is that the radial velocity reported in cuts were applied by Sartoretti et al. (2018) prior to the data release. Additionally, the spectra of all stars where $T_{\text{eff}} > 7000 \text{ K}$. Medium-period solutions is $20 \text{ km s}^{-1}$ greater than $14 \text{ mag}$. Marchetti et al. (2018a) for high-velocity stars was to require that $P > 70 \text{ d}$. $P < 40 \text{ d}$. $P < 70 \text{ d}$. Bottom: posterior radial velocity tracks for orbits with $P > 70 \text{ d}$.

593...064 is explained by a stellar evolutionary process. The short period or velocity amplitude of that binary. In summary, our $593...064$ is explained by a stellar evolutionary process. The short period or velocity amplitude of that binary. In summary, our solutions imply a secondary mass with the star being in a close stellar binary. The medium-period solutions imply a secondary mass $M_2$ and separation $a$ of $M_2 = 1.1^{+0.5}_{-0.3} \text{ M}_\odot$ and $a = 94^{+16}_{-8} \text{ R}_\odot$, while the short-period solutions have $M_2 = 0.4^{+0.7}_{-0.3} \text{ M}_\odot$ and $a = 33^{+0.7}_{-0.5} \text{ R}_\odot$. The systemic velocity of the medium-period solutions is $-62.5 \pm 5.0 \text{ km s}^{-1}$.

3.2 Scenario 2: the Gaia measurement is spurious

The counter scenario is that the radial velocity reported in Gaia DR2 is spurious. One could argue that this is unlikely, because quality cuts were applied by Sartoretti et al. (2018) prior to the data release. Katz et al. (2019) summarize these cuts as removing:

(i) Stars with an uncertainty on their position greater than 100 mas.
(ii) Stars where the $G_{\text{RVS}}$ derived from their RVS spectrum was greater than 14 mag.
(iii) Stars where all of their transits are flagged as ambiguous.
(iv) Stars with a radial velocity uncertainty greater than $20 \text{ km s}^{-1}$.
(v) Stars where more than 10 per cent of the transits were detected as being doubly lined spectroscopic binaries.
(vi) Stars that were detected to be emission line stars.
(vii) Stars where the template has $T_{\text{eff}} \leq 3500 \text{ K}$ or $T_{\text{eff}} \geq 7000 \text{ K}$.

Additionally, the spectra of all stars where $|\text{RV}| > 500 \text{ km s}^{-1}$ were visually inspected. A further cut applied in the search by Marchetti et al. (2018a) for high-velocity stars was to require that $\text{RV}_{\text{NB,TRANSITS}} > 5$, and this cut has been used widely in the literature. If the measurement is spurious then it must be spurious in a way that neatly avoids the quality cuts in these earlier works and thus the star must be in some way unusual.

There are two properties of Gaia DR2 593...064 that make it slightly unusual among the RVS stars. First, its $G_{\text{BP}}$ magnitude of 13.2 places it in the faintest 2 per cent of Gaia DR2 RVS stars. Secondly, as mentioned in Section 3.1, Gaia DR2 593...064 has the most other Gaia sources within 8 arcsec of the 34 stars that both meet all the criteria above and have $|u| > 500 \text{ km s}^{-1}$.

The reason to be concerned by the many nearby stars is that it is possible for the light from two stars to blend together in a single RVS spectrum. The Gaia RVS is an integral-field spectrograph operating in time delay integration mode, with the result that windows need to be selected around the spectra of individual stars (i.e. there is a conveyor belt of spectra continually being read out). The RVS CCDs see a changing wavelength region for each star as Gaia scans across the sky, and thus the overall wavelength scale of each spectra must be determined from the known position of the star from Gaia astrometry. When RVS spectra overlap each other on the CCD their windows are truncated in the across scan (AC) direction, reducing their AC width down from the nominal 10 pixels. The truncation is designed to share the flux from the two spectra between the two windows so that each window could be deblended from the other; however, there was no attempt in Gaia DR2 to deblend windows, which means that a single window can contain two different spectra with two different wavelength scales. To mitigate the issue of blended windows, all those windows that were truncated in a non-rectangular pattern were filtered out of the RVS pipeline. Windows that were truncated in a rectangular pattern were let through because most of the time they were truncated by very faint spurious sources. Spurious sources are detected onboard around and along the diffraction spikes of sources brighter than about 16 mag in the SkyMapper CCDs (Fabricius et al. 2016; not to be confused with the SkyMapper Survey). If the spurious source is brighter than the onboard magnitude $G_{\text{RVS}} = 16.2$ then it also gets an RVS window. RVS windows only start or end on multiples of 105 pixels (before 2015 June) or 108 pixels (after 2015 June), called ‘macrosample boundaries’ (Cropper et al. 2018); 105 and 108 pixels correspond to approximately 6.2 and 6.4 arcsec, respectively. Two sources with angular separations in the along scan (AL) direction smaller than these values will have RVS windows starting on the same macrosample boundary. Approximately 40 per cent of the stars with onboard magnitude $G_{\text{RVS}}$ between 7 and 9 have a spurious source sufficiently close that the brighter window is truncated in the AC direction, such that its AC size is 5 pixels instead of the normal 10, but the two windows are aligned in AL so that the brighter window remains rectangular (Sartoretti et al. 2018). While most truncated windows with rectangular geometries will be due to a spurious source, some spectra containing a contribution from a second bright star will also have been let through.

The implication is that if Gaia scans across two stars that are lined up parallel to the AL direction and have an angular offset along the AL direction of less than 6.4 arcsec (resulting in a rectangular truncation), then their light can be blended into one Gaia DR2 RVS spectrum, but with the light from each star offset$^3$ by $145.1 \text{ km s}^{-1} \text{ arcsec}^{-1}$, depending on the wavelength

$^3$Cropper et al. (2018) state that the pixels in the along scan direction are 0.0589 arcsec long and that the dispersion varies from $8.51 \text{ km s}^{-1} \text{ pix}^{-1}$ at $847 \text{ nm}$ to $8.58 \text{ km s}^{-1} \text{ pix}^{-1}$ at $873 \text{ nm}$, which corresponds to $144.5 - 145.7 \text{ km s}^{-1} \text{ arcsec}^{-1}$ with a mean of $145.1 \text{ km s}^{-1} \text{ arcsec}^{-1}$.
under consideration. As mentioned above, this is not a problem in a majority of cases because the other source is usually very faint and spurious. Nevertheless, in a small number of cases the other source may be bright in the \( G_{RVS} \) band and thus could have interfered with the RVS measurement. This interference can range from a small shift in the line centroid to the introduction of a much stronger line, which shifts the RVS measurement by hundreds of \( \text{km s}^{-1} \). We should expect many of the cases where there are two lines to have been filtered out by the doubly lined spectroscopic binary cut above.

Contamination of the RVS spectrum of Gaia DR2 593...064 by the light of a nearby star can explain the anomalous radial velocity but would require a star bright in \( G_{RVS} \). The \( G_{RVS} \) was not published in Gaia DR2, but, as a proxy, we can say that a star is sufficiently bright to interfere if either it itself has an RVS measurement or it is at least as bright as Gaia DR2 593...064 in \( G_{RP} \). Indeed, as mentioned previously, Gaia DR2 593...352 lies only 4.284 arcsec away. This corresponds to a velocity offset of 619.0–624.2 \( \text{km s}^{-1} \). Gaia DR2 593...352 has a radial velocity reported in Gaia of 5.40 ± 2.85 km s\(^{-1}\); and thus subtracting the velocity offset from the true radial velocity gives \(-613.6–618.8 \text{km s}^{-1}\), which encompasses the reported radial velocity for Gaia DR2 593...064 of \(-614.3 ± 2.5 \text{km s}^{-1}\). The anomalous radial velocity reported for Gaia DR2 593...064 can be fully explained if the spectra used to determine the radial velocity were blended with those of Gaia DR2 593...352 in each of the seven radial velocity transits.

The scenario outlined above requires that most of the seven radial velocity transits occurred during Gaia scans that passed across both stars. The Gaia Observation Forecasting Tool (GOST) provides both the dates and scanning angles of the possible radial velocity measurements; however, as discussed above, we do not know which 7 of these 42 possibilities actually contributed to the RVS measurement. The small standard deviation of the radial velocity measurements (5.17 km s\(^{-1}\)) provides one clue: If even a single transit gave a measurement of the true radial velocity of Gaia DR2 593...064 then the standard deviation would be much greater. Thus, looking at Fig. 4, it seems quite likely that all seven transits will have occurred in the 3.75-d window. In Fig. 7, we show the 26 Gaia scans that occurred over that time period. These scans all pass through the nearby bright star Gaia DR2 593...352 and thus it is likely that all seven RVS spectra are blends of the light from both stars.

We conclude that it is highly likely that the radial velocity measurement reported in Gaia DR2 is spurious and thus that Gaia DR2 593...064 has a systemic velocity along the line of sight of \(-62.5 ± 5.0 \text{km s}^{-1}\). Assuming the system has a radial velocity of \(-62.5 \text{km s}^{-1}\) with proper motion \((\mu_\alpha \cos \delta, \mu_\delta) = (-2.676, -4.991) \text{mas yr}^{-1}\) at a distance of 2.08 kpc, we find that Gaia DR2 593...064 is a typical disc star with position \((R, z) = (6.3, -0.1) \text{kpc and velocity} (u_R, u_\phi, u_z) = (33, 288, -7) \text{km s}^{-1}\). It is likely that Gaia DR2 593...064 is co-moving with Gaia DR2 593...576, further strengthening this conclusion.

### 3.3 Implications for Gaia DR2 radial velocities

If the cuts described in the previous section failed to catch the spurious measurement of Gaia DR2 593...064 then it is possible that there are more stars that suffer similar issues. For each star in Gaia RVS, we query in the full Gaia DR2 catalogue whether there is another source within 6.4 arcsec that either has an RVS measurement or is at least as bright in \( G_{RP} \). This applies to 63 764 of the Gaia RVS stars. Many of these pairings will not have resulted in blended spectra, but because of the limited data published in Gaia DR2 and the infeasibility of subjecting every one of these sources to the same treatment we have performed on Gaia DR2 593...064, we recommend cutting these sources.

One complication is that the \( G_{RP} \) and \( G_{BP} \) pipeline was more conservative in its treatment of blends than the RVS pipeline, and discarded the colours of stars where blends were suspected. A star not having a \( G_{RP} \) measurement can thus be suggestive of a blend. Note that Gaia DR2 593...352 is one of the 10 976 Gaia RVS sources that are missing one or both of \( G_{BP} \) and \( G_{RP} \). We recommend cutting all RVS sources missing either of these photometric bands. We also extend the neighbour-blending criteria above to encompass nearby stars that are at least as bright in \( G \), which increases the number of suspect Gaia RVS stars to 70 365.

Another way to flag Gaia DR2 radial velocities as not representative of the systemic velocity of the system or suspicious is if the variance across the individual radial velocity measurements is unusual. We expect that the variance should be primarily a function of \( G_{BP} \) and \( G_{BP} - G_{RP} \) (for instance, hot stars will have smaller and broader lines), and thus an unusually large or small variance could indicate that the radial velocity cannot be trusted. An unusually large variance could be caused by the star being in a binary; singly lined spectroscopic binaries were not treated in the Gaia DR2 RVS pipeline. Alternatively, if a star has an unusually small variance that could signal a star whose spectrum was dominated by the light of a nearby brighter star, because then the uncertainty on the radial velocity will be the relatively smaller uncertainty of a brighter star. We defer the proper investigation of the Gaia DR2 radial velocity variances to a forthcoming paper (Boubert et al., in prep.); however, we do suggest that stars with too few RV transits should be removed based on the following argument.

Suppose that \( Gaia \) makes \( N \) radial velocity measurements of a star and that those radial velocity measurements are drawn from a

![Figure 7. The seven radial velocity measurements of Gaia DR2 593...064 were likely made during a subset of the 26 scans that are shown as orange lines (fixed to pass through the centre of that star). These scans all pass through the nearby bright star Gaia DR2 593...352 and thus it is likely that all seven RVS spectra are blends of the light from both stars. Note that the SkyMapper image has been flipped with respect to Fig. 1.](https://academic.oup.com/mnras/article-abstract/486/2/2618/5304184)
Gaussian centred on the true mean radial velocity with a standard deviation of $\sigma$. It then follows that the variance $S^2 = S(v_t)^2$ of those radial velocity measurements will have as its sampling distribution

$$\frac{(N-1)S^2}{\sigma^2} \sim \chi^2_{N-1}. \quad (2)$$

This equation implies that the likelihood of observing a radial velocity variance $S^2$ given the number of observations $N$ and true variance $\sigma^2$,

Likelihood $(S^2| N, \sigma^2) = \frac{(N-1)}{\sigma^2} \chi^2_{N-1} \left(\frac{(N-1)S^2}{\sigma^2}\right). \quad (3)$

The value of $\sigma^2$ that maximizes this likelihood is $S^2$ for all $N > 1$. Note, however, that this likelihood is not a well-defined probability density function for $N < 4$, because its integral does not converge over the region $(0, \infty)$. While we can resolve this by specifying a prior on $\sigma^2$ and using the Bayesian posterior rather than maximum likelihood estimation to obtain a most likely value, this improper behaviour suggests that any constraint we infer on $\sigma^2$ for stars with $N < 4$ will be too broad to rule on whether such stars are single or binary. We therefore recommend an additional quality cut that requires the number of transits $N \geq 4$. While the justification above is qualitative in nature, there is a further reason to cut stars with few transits: A cut on $N$ acts to remove stars with blended spectra, because the probability that the $N$ transits are sufficiently aligned decreases with increasing $N$.

In summary, we recommend three novel quality cuts that could be applied to the Gaia RVS sample. We list these here in order of increasing complexity:

(i) The star must have reported $G_{BP}$ and $G_{RP}$ magnitudes.

(ii) The radial velocity must be based on at least four transits (e.g. $\text{RV\_NB\_TRANSITS} \geq 4$).

(iii) The star must not have a neighbour within 6.4 arcsec that either itself is in RVS or that is brighter in $G$ or $G_{RP}$.

The first and third cuts aim to exclude sources with radial velocities that are suspected to be contaminated. This paper finds one source that is highly likely to be contaminated but it is possible that these cuts will also exclude uncontaminated sources with valid radial velocities. The first and third cuts will obtain the cleanest possible sample (in terms of contamination) but at the expense of completeness. The second cut removes sources where the number of transits is too few to determine whether the radial velocity is representative of the systemic velocity of the system. This may remove sources where the radial velocities are actually representative of the systemic velocity of the system. Similarly to the other cuts, the second cut will obtain the cleanest possible sample (in terms of well-behaved radial velocity variances) but at the expense of completeness. Therefore, the applicability of these cuts depends on the science question being addressed.

We demonstrate the efficacy of these cuts in Fig. 8. The final clean sample contains 6,145,608 stars, which is many more than the 4,809,107 that survive the commonly used $\text{RV\_NB\_TRANSITS} > 5$ cut. Of the 202 stars with radial velocities greater than 500 km s$^{-1}$, only 90 survive the four cuts. To aid the reader in implementing the nearby bright companion cut, we give the necessary information in Table 4.

This work investigated the most likely of the hypervelocity candidates proposed by Marchetti et al. (2018a), Hattori et al. (2018), and Bromley et al. (2018); however, we checked whether the issue of unreliable Gaia DR2 radial velocities affects any of the other candidates in the literature. We cross-matched The Open Fast Stars Catalog (Boubert et al. 2018) against our list of stars with unreliable radial velocities and identified two additional candidates that may suffer from these issues. Gaia DR2 5958197813784543872 (otherwise known as 2MASS J17464606–3937523) was proposed by Kunder et al. (2012) as a possible hypervelocity star based on their measured 447 km s$^{-1}$, although those authors commented that its metallicity of $[\text{Fe/H}] = -0.86 \pm 0.05$ is consistent with it.
being a bound bulge star. This star was flagged because the median Gaia DR2 radial velocity of $421.63 \pm 3.09 \, \text{km s}^{-1}$ is based on only two measurements; however, we note that this radial velocity is consistent with the value reported by Kunder et al. (2012). The other flagged star is Gaia DR2 5300505902646873088 (otherwise known as Gaia-T-ES2), which is a $G_{BP} = 12.4$ star ranked by Hattori et al. (2018) as the second most likely unbound candidate in their list. The Gaia radial velocity of $160.22 \pm 4.00 \, \text{km s}^{-1}$ was flagged because it is based on only three measurements.

### Table 4: List of all sources in Gaia RVS that have a companion in the full Gaia DR2 catalogue within 6.4 arcsec that either itself is in Gaia RVS or that is brighter in $G_{BP}$ or $G$. The columns are the Gaia DR2 ID, the number of companions that are in RVS, the number of companions brighter in $G_{BP}$, and the number of companions brighter in $G$. Only the first five rows are shown here and the full table is available in a supplementary data file online.

| SourceID                  | $N_{\text{RVS}}$ | $N_{\text{BP}}$ | $N_{G}$ |
|---------------------------|-------------------|-----------------|--------|
| 83154861954304             | 0                 | 1               | 1      |
| 7396666383070976           | 0                 | 1               | 0      |

### 4 CONCLUSIONS

Gaia DR2 593...064 was proposed by Marchetti et al. (2018a) and Bromley et al. (2018) to be a likely hypervelocity star based on the incredible radial velocity $−614.3 \pm 2.5 \, \text{km s}^{-1}$ reported in Gaia DR2. Bromley et al. (2018) suggested that this star may be in a crowded field due to its proximity to the Galactic plane; taking images from SkyMapper, we found that the star is indeed in a crowded field surrounded by several relatively bright stars. Motivated by this, we obtained eight epochs of ground-based spectroscopic follow-up with the SOAR telescope. From these spectra, we measured a median radial velocity of $−56.5 \pm 5.3 \, \text{km s}^{-1}$, which is seemingly inconsistent with the radial velocity reported in Gaia DR2. Analysis of the eight spectra determined that Gaia DR2 593...064 is an A-type main-sequence or sub-giant star, and that the star is not spectroscopically unusual in a way that could explain the discrepancy.

The Gaia measurement is based on seven individual radial velocity measurements taken from seven RVS transits, each transit corresponding to three RVS CCD spectra. Neither the individual measurements nor the dates on which they were taken are publicly available; however, it seems likely that some of the seven measurements were taken during a 3.75-d window beginning on 2015 July 7. This allowed us to infer that if the Gaia measurement is correct then the star must be in orbit around an intermediate-mass black hole, which suggests that the Gaia datum is likely spurious. By contrast, the eight radial velocities we obtained show evidence for binary motion with a period of less than 70 d and we constrained the likely parameters of that binary.

The spurious Gaia radial velocity is most probably caused by light from a nearby bright star blending with the spectrum of Gaia DR2 593...064. The Gaia RVS is an integral field spectrograph that operates in time delay integration mode, and thus the angular offset between the two stars translates to a velocity shift of the contaminating spectrum relative to that of Gaia DR2 593...064 at a rate of 145.1 km s$^{-1}$ arcsec$^{-1}$. This effect relies on all seven scans passing across both stars and thus makes it highly likely that all seven transits occurred in the 3.75-d window beginning on 2015 July 7.

That the reported radial velocity of Gaia DR2 593...064 could be so badly wrong begs the question: How many other Gaia DR2 RVS sources are susceptible? We find that any star with a companion closer than 6.4 arcsec that either itself has an RVS measurement or that is brighter in $G$ or $G_{BP}$ could be suspect. For the cleanest possible sample (in terms of contamination), we also recommend that RVS stars without $G_{BP}$ or $G_{RP}$ should be cut, because one reason for the absence of colour photometry is if the pipeline detected a blend in the BP/RP spectra. The radial velocity variances of single Gaia RVS stars should be a simple function of $G_{BP}$ and $G_{BP} − G_{RP}$, and thus stars with an excessively large radial velocity variance are likely in a singly lined spectroscopic binary (a possibility that is not treated in the RVS pipeline for Gaia DR2). While we leave a full analysis of the radial velocity variances to a forthcoming work (Boubert et al., in prep.), we argue that the radial velocity variance of stars with three or fewer transits cannot provide strong enough evidence that the radial velocity variance is well behaved, and thus, for the cleanest possible sample (in terms of well-behaved radial velocity variances), we recommend that only stars with four or more transits be used. These cuts are effective: They remove almost all of the sources that have large radial velocities or are too faint to have had a true RVS measurement in DR2, whilst retaining 85 per cent of the stars.

Many of the issues that our three cuts target will be handled by the RVS pipeline in future Gaia data releases. However, at the time of writing, the third Gaia data release will not be until the first half of 2021. The cuts presented in this work will unlock the full potential of Gaia DR2 radial velocities and open the door to progress in Galactic dynamics over the two years prior to DR3.

### ACKNOWLEDGEMENTS

The authors would like to thank Morgan Fraser, David Katz, Payel Das, Keith Hawkins, and Lachlan Lancaster for useful discussions. This work is an offshoot of the D 6 collaboration of theorists and observers hunting for hypervelocity white dwarfs. DB thanks Magdalen College for his Fellowship by Examination. SUPPORTING INFORMATION
Supplementary data are available at MNRAS online.

Table 4. List of all sources in Gaia RVS which have a companion in the full Gaia DR2 catalogue within 6.4 arcsec that either itself is in Gaia RVS or that is brighter in $G_{RP}$ or $G$. The columns are the

5http://www.astropy.org

Gaia DR2 ID, the number $N_{RVS}$ of companions that are in RVS, the number $N_{RP}$ of companions brighter in $G_{RP}$ and the number $N_{G}$ of companions brighter in $G$.

APPENDIX: POSTERIOR CORNER PLOT FOR ATMOSPHERIC AND STELLAR PARAMETERS
Figure A1. Corner plot of the posterior samples of the effective temperature $T_{\text{eff}}$, surface gravity $\log g$, mass, and radius of Gaia DR2 593...064. The procedure that resulted in this plot is described in detail in Section 2.
