Abstract

Background Helicobacter pylori (H. pylori) is a well-recognized gastroduodenal pathogen and class I carcinogen. Dual oxidase-2 (DUOX2), a member of NADPH oxidase family, has several critical physiological functions, including thyroid hormone biosynthesis and host mucosal defense.

Aim To investigate the effect of H. pylori infection on DUOX2 gene expression in human stomach.

Materials and Methods The biopsies were obtained from patients who underwent endoscopic diagnosis. The patient serum was assayed for two virulence factors of H. pylori, CagA IgG and VacA. The inflammation in gastric mucosa was analyzed with histology. Real-time quantitative PCR was used to detect the expression of three members of NADPH oxidase, NOX1, NOX2, and DUOX2, as well as lactoperoxidase (LPO) in the gastric mucosa. NOX2, DUOX2, and myeloperoxidase (MPO) protein levels were quantified by Western blots or immunohistochemistry.

Results The H. pylori-infected gastric mucosa had more severe inflammation than uninfected samples. However, the expression of DUOX2 mRNA and protein was lower in gastric mucosa of patients with H. pylori infection compared to the uninfected. Among the H. pylori-infected patients who underwent endoscopic diagnosis. The patient serum was assayed for two virulence factors of H. pylori, CagA IgG and VacA. The inflammation in gastric mucosa was analyzed with histology. Real-time quantitative PCR was used to detect the expression of three members of NADPH oxidase, NOX1, NOX2, and DUOX2, as well as lactoperoxidase (LPO) in the gastric mucosa. NOX2, DUOX2, and myeloperoxidase (MPO) protein levels were quantified by Western blots or immunohistochemistry.

Results The H. pylori-infected gastric mucosa had more severe inflammation than uninfected samples. However, the expression of DUOX2 mRNA and protein was lower in gastric mucosa of patients with H. pylori infection compared to the uninfected. Among the H. pylori-infected
patients, those having CagA IgG or VacA in the serum had lower DUOX2 expression levels than those infected with *H. pylori* without either virulence factor. The NOX2 and MPO levels were higher in those patients infected with *H. pylori* irrespective of the virulence factors than those uninfected patients. NOX1 and LPO mRNA were undetectable in the gastric mucosa.

**Conclusion** CagA+ or VacA+ *H. pylori* in the stomach of patients may suppress DUOX2 expression to promote its own survival. Increased NOX2 could not eliminate *H. pylori* infection.

**Keywords** Dual oxidase-2 (DUOX2) · Gastric mucosa · *Helicobacter pylori* (*H. pylori*) · Lactoperoxidase (LPO) · NOX2

**Introduction**

*Helicobacter pylori* (*H. pylori*) is a Gram-negative, microaerophilic bacterium that colonizes the luminal surface of the gastric epithelium [1]. Approximately half of the world’s population is infected with *H. pylori*, and 15–20% of the infected individuals develop clinical diseases [2]. *Helicobacter pylori* is a well-recognized gastroduodenal pathogen and a group I carcinogen. *Helicobacter pylori* can cause duodenal and gastric ulcers, non-ulcer dyspepsia, gastric carcinoma, and gastric mucosa-associated lymphoid tissue (MALT) lymphoma [3, 4]. However, recent evidence suggests that *H. pylori* protects against esophageal reflux, Barrett’s esophagus [5, 6], allergy, asthma [7], and even inflammatory bowel diseases [8]. Most microorganisms cannot survive the gastric acidity. However, *H. pylori* is able to secrete urease, which hydrolyzes urea to produce alkaline ammonia, thus promotes its own survival in the stomach [4]. Furthermore, *H. pylori* is resistant to the immune responses that it activates in gastric mucosa by using a highly sophisticated mechanism contributed by pathogenicity-related factors [9–11].

Several virulence factors of *H. pylori*, including urease, cytotoxin-associated gene A (CagA), and vacuolating cytotoxin A (VacA), are used clinically for strain diagnosis and virulence judgment [12, 13]. CagA, one of the most abundant *H. pylori* proteins, is translocated into epithelial cells by type IV secretion system [14]. The CagA gene is located in the 47-kb Cag pathogenicity island (Cag-PAI), which consists of approximately 27 genes. Cag-PAI-containing *H. pylori* is more virulent, partially due to the fact that Cag-PAI genes also encode type IV secretion system [15, 16]. CagA facilitates *H. pylori* colonization in gastric mucosa by disrupting the gap junctions, cell polarity, and modulation of signal pathways to stimulate proliferation [14, 17, 18]. VacA is a secreted protoxin, which is internalized through interference with membrane trafficking of gastric epithelial cells. Once getting inside of the cells, VacA causes cytochrome C release and cell apoptosis by destabilizing mitochondria [19].

*Helicobacter pylori* infection will elicit host immune responses with varied intensities depending on the bacterial strain and virulence. Pro-inflammatory cytokines, enzymes, and reactive oxygen species (ROS) produced by gastric epithelial cells and inflammatory cells (i.e., neutrophils and monocytes) all contribute to inflammation [20]. There are seven members in the family of ROS-generating nicotinamide adenine dinucleotide phosphate (NADPH) oxidase, including NOX1–5 and two dual oxidases (DUOX1 and DUOX2). NADPH oxidases are transmembrane proteins that accept electrons from cytosolic NADPH, transport them through flavin adenine dinucleotide (FAD), membrane-imbedded hemes, and then donate a single electron to reduce oxygen to superoxide [21]. NOX1 is highly expressed in the normal colon epithelium and plays a role in intestinal inflammation [22–24]. Guinea pig gastric NOX1 is highly responsive to lipopolysaccharide from *H. pylori* to generate peroxide anion [25].

NOX2 is the prototype NADPH oxidase and is referred to as the phagocyte NADPH oxidase because it was first described in neutrophils and macrophages [26]. The distribution of NOX2 is not limited to phagocytes; other type of cells, such as lymphocytes, neurons, and endothelium, also express NOX2 [26, 27]. NOX2 is a major ROS-producing enzyme with bactericidal activity [22]. Here, we investigated the levels of NOX2 and myeloperoxidase (MPO), the most abundant neutrophil granule proteins, as inflammation markers in the gastric mucosa.

DUOXs have an intrinsic Ca2+-NADPH-dependent H2O2-generating activity [28]. DUOX2, but not DUOX1, was found in the epithelium of the digestive tract [29]. The physiological functions of DUOX2 include thyroid hormone biosynthesis and host mucosal defense [21]. A putative mechanism of action is via DUOX-LPO–SCNn system, in which the DUOX-produced H2O2 and the ubiquitous thiocyanate (SCN−) are catalyzed by LPO to form bactericidal isothiocyanate (OSCN−) in the airway.
salivary gland, and intestinal mucosal epithelial cells [30–33]. The DUOX2 and LPO are highly expressed in the lower GI tract, especially in the rectum [22, 34]. Increased DUOX2 expression was found in colonic epithelial cell in patients with inflammatory bowel disease [35–37]. Moreover, DUOX2 is regulated by NOD2 upon ligand binding in the intestine [36]. In animal studies, DUOX2 gene expression is elevated in the H. pylori-infected stomach of rhesus macaques in a Cag-PAI-dependent manner [38] and in the Salmonella typhimurium-infected mouse colon [39]. DUOX2 prevented H. felis infection and consequently reduced inflammation in the mouse stomach [40]. Whether DUOX2 gene expression is also activated by H. pylori colonization in human gastric mucosa is unclear.

In this study, we investigated NADPH oxidase, NOX1, NOX2, DUOX2, LPO, and MPO expressions in the gastric biopsies of patients with and without H. pylori infection. Higher inflammation scores, NOX2 and MPO expression levels were detected in the samples from H. pylori-infected patients compared to those uninfected. Unexpectedly, the DUOX2 protein and mRNA levels were lower in patients infected with CagA+ or VacA+ H. pylori than patients infected with H. pylori without virulence factors and uninfected patients. The latter two groups had the same DUOX2 mRNA levels. We speculate that the virulence factors of H. pylori may inhibit DUOX2 gene expression in human gastric mucosa.

### Materials and Methods

#### Tissue Procurement

Gastric biopsies were obtained from patients with alimentary tract symptoms who underwent endoscopic diagnosis at the First Affiliated Hospital of Henan University of Science and Technology. To ensure accurate histopathological diagnosis, minimally four biopsies of gastric mucosa were collected during endoscopy at 2.5-cm-circle area from the pylorus, as well as one from gastric incisura angularis for the study. More biopsies were taken from the abnormal areas for pathological diagnosis. One biopsy was used for rapid urease test (RUT). One biopsy was fixed in 10 % formalin, embedded in paraffin, and then sectioned. The sections were stained with hematoxylin and eosin (H&E) for pathological scoring and for IHC staining. The remaining samples were stored at −80 °C for RNA extraction and Western blotting. RNAlater (Qiagen, Hilden, Germany, Cat. No. 76106) was used to prevent RNA degradation. Patient serum was collected during endoscopy and was tested for CagA IgG and VacA using enzyme-linked immunosorbet assays (ELISA). The clinical data collected from each patient included age, gender, medical history, medication usage, and endoscopy diagnosis (Table 1). Patient exclusion criteria were as follows: (1) undergoing proton pump inhibitor and antibiotic treatment, such as amoxicillin and clarithromycin, within 1 month of biopsy; (2) having esophageal or gastric cancers; (3) upper gastrointestinal bleeding; (4) severe disease in the liver, kidney, cardiovascular or cerebrovascular system; and (5) pregnant or breast-feeding. Informed consent was obtained from all patients, and the study was approved by the Clinical Research Ethics Committee of the Hospital.

#### Diagnosis of H. pylori Infection and Diseases

Both RUT and C13 or C14 urea breath test (UBT) were used to determine H. pylori infection without performing colony-forming assay. When either one was positive, the patient was considered colonized with H. pylori. The diagnosis of chronic superficial gastritis and atrophic gastritis was based on endoscopy and pathology [41, 42]. Intestinal metaplasia (IM) was diagnosed by the presence of goblet cells. The gastric and duodenal ulcers were diagnosed by endoscopy.

#### Histological Analysis

The criteria for inflammation scores in gastric mucosa were based on the Updated Sydney System [41]. The pathologic features included (1) neutrophil infiltration, (2) monocyte infiltration, (3) atrophy, and (4) IM. The score for each feature is the following: normal to very mild as 0, mild as 1, moderate as 2, and marked to severe as 3. The total scores for normal tissue are below 4. The visual analogue scale was applied to microscopic examination results [41, 43].

| Table 1 Clinical features of gastric biopsies |
|---------------------------------------------|
| Hp+/total        | Hp+/gender | Age (year)* |
| Male     | Female    | Male/female |
|-----------------|------------|-------------|
| Superficial gastritis | 68/132     | 39/71       | 29/61       | 54/53       |
| Atrophic gastritis    | 1/5        | 0/2         | 1/3         | 66/58       |
| Gastric ulcer       | 27/43      | 19/25       | 8/18        | 52/53       |
| Duodenal ulcer     | 15/20      | 11/15       | 4/5         | 43/46       |
| Total             | 111/200    | 69/113      | 42/87       |

* The patient’s age ranges from 18 to 70 years
detected with biotinylated monoclonal antibodies. After incubation with streptavidin–horseradish peroxidase (HRP) for 30 min, the peroxidase activity was analyzed with the addition of chromogenic substrate 3,3',5,5'-tetramethyl benzidine and hydrogen peroxide. After 15 min at room temperature, the reaction was stopped with H$_2$SO$_4$ and the absorbance was measured at 450 nm. According to the manufacturer’s specifications, above 1.2 ng/mL CagA IgG or 142 pg/mL VacA is considered positive (+).

### IHC

Four-micron sections of paraffin-embedded samples were mounted on poly-L-lysine-coated slides. IHC was performed using a modified biotin–peroxidase complex method as described [44]. Briefly, tissue sections were dewaxed in xylene, rehydrated through graded alcohol, and the antigen retrieval was done by microwave-boiling the slides for 10 min in 0.1 N sodium citrate, pH 6.0. The endogenous peroxidase was blocked by incubating in 3 % H$_2$O$_2$ for 10 min in 0.1 N sodium citrate, pH 6.0. The endogenous retrieval was done by microwave-boiling the slides for 15 min at room temperature. After 15 min at room temperature, the peroxidase activity was analyzed with the addition of streptavidin–horseradish peroxidase (HRP) and visualized with 3,3-diaminobenzidine substrate. A goat anti-NOX2 Ab (1:100 dilution, Santa Cruz, CA, USA, Cat. No sc-5826) and a biotinylated rabbit anti-goat Ab (1:300 dilution) (Boster Biological Technology Co., Ltd, Wuhan, China, Cat. No SA1023) were used as to detect NOX2. The sections were counterstained with hematoxylin. The positive control for anti-DUOX2 Ab was thyroid gland tissues, and the negative controls were either omitting the primary Ab or using an unrelated rabbit Ab.

The protein levels were evaluated blindly in 10 fields under 400× magnification from each slide. One hundred cells per field were categorized as follows: “−,” 0 %, no staining; “+,” >25 % cells were stained; “++,” 26–50 % cells were stained; and “+++,” >50 % cells stained.

### Real-Time qPCR

Total RNA was extracted using TRIzol Reagent (Invitrogen, USA). Two µg of total RNA was used for cDNA synthesis using PrimeScript™ RT Master Mix (Takara, Japan) in a 40-µl reaction mixture, following these steps: 37 °C for 15 min, 85 °C for 5 s, and 4 °C for 10 min. The primer sequences for DUOX2, NOX1, NOX2, LPO, MPO, and β-actin (Table 2) were designed by using Primer3.0 software [45] and synthesized by Sangon Biotechnology (Zhengzhou, China). Real-time qPCR was done with a CFX96™ Real-Time PCR system (Bio-Rad Labs, USA). In 25-µl reaction mixture contained 2 µl of cDNA, 12.5 µl of 2 x SYBR Premix Ex Taq II (Takara, Japan), 8.5 µl of H$_2$O, and 2 ul of 0.4 µM primers. A two-step method was used for DUOX2, NOX1, LPO, and β-actin cDNAs detection because of the 60 °C annealing temperature; the reaction had an initial step of 95 °C for 30 s and 40 cycles of 95 °C for 5 s plus 60 °C for 30 s. A three-step method (40 cycles of 95 °C for 5 s, 57 °C for 30 s, and 72 °C for 30 s) was used for NOX2 cDNA, which had 57 °C annealing temperature. Each sample was assayed in triplicates. The efficiency of PCR amplification was 97–105 %. A melting curve was performed to evaluate product specificity. RNA levels were quantified using the Ct ($2^{-\Delta\Delta Ct}$) method and normalized to β-actin. The gene is considered as not expressed when the Ct value is higher than 35.

### Western Blotting Analysis

Protein lysates were prepared from tissues by homogenization in RIPA lysis buffer (Soliarbio Co., Beijing,

---

**Table 2** Primer sequence for quantitative real-time PCR

| mRNA   | Gene     | Primer sequence  | Amplicon (bp) |

| NM-001101 | β-actin  | 5'-AGCAGCTGTGTGGCGCTACAG | 116           |
Among the 200 patients recruited in the study, 113 patients had H. pylori infection, 58.5% of patients (n = 48) were negative for both CagA and VacA (CagA-/VacA-), 9.7% (n = 8) were CagA-/VacA+, 13.4% (n = 11) were CagA+/VacA-, and 18.3% (n = 15) were double positive (CagA+/VacA+). The CagA IgG+ rate in our study was also similar to other studies conducted in China [47].

**Helicobacter pylori+ Patients Had Higher Inflammation in Gastric Mucosa than Uninfected Patients**

We analyzed the inflammation scores and compared the scores between the H. pylori-negative (Hp−) and H. pylori-positive (Hp+) groups (Table 3). The pathology scores were based on inflammation, atrophy, and intestinal metaplasia (IM). The inflammation, but not atrophy or IM, was significantly higher in the Hp+ group.

We also compared the inflammation scores between the Hp+ and Hp− groups as well as among the subgroups of Hp+ patients based on CagA IgG and VacA in their serum (Fig. 1a, b). The inflammation scores in gastric mucosa of Hp+ patients were significantly higher than Hp− group. Also, the inflammation scores of patients of CagA+/VacA+ group are significantly higher than CagA−/VacA− group (Fig. 1b). However, the inflammation scores of patients positive for CagA IgG or VacA+ H. pylori infection were not different from any other infected groups.

**Detection of Pro-Oxidant Gene Expression by qPCR**

NOX2 protein is highly expressed in the neutrophils and macrophages, which are recruited into the inflammatory sites by H. pylori infection [48]. The NOX2 mRNA level is twofold higher in the gastric mucosa of Hp+ patients than in Hp− patients, and no difference is found among the infected groups stratified with CagA and VacA status (Fig. 2a and Supplementary Figure 1A).

Because DUOX2 protected against *Helicobacter felis* infection in mouse stomach [40], we analyzed DUOX2 mRNA levels in our patients. Unexpectedly, the DUOX2 mRNA levels were significantly higher in Hp− patients compared to Hp+ patients (P = 0.002).

### Statistical Analysis

Student’s *t* test and Mann–Whitney *U* test were used to assess the difference in each pair. One-way ANOVA and Kruskal–Wallis tests were used to compare the data among at least three groups. Significant difference was defined as *P* < 0.05. Data were reported as mean ± standard error of the mean (SEM). All statistical analysis was performed using the SPSS 19.0 statistics package (SPSS Inc., Chicago, IL, USA).

### Results

**Helicobacter pylori Infection Rate and Distribution of CagA+ IgG and VacA+ in Patients with Gastritis**

Among the 200 patients recruited in the study, 113 patients were male and 87 were female (Table 1). Besides the higher disease incidence in males than females, there was no gender difference in disease characteristics. The average ages of male and female were 53.5 and 52.7 years. Most patients (66%, 132/200) had chronic superficial gastritis; other patients had atrophic gastritis (2.5%, 5/200), gastric ulcer (21.5%, 43/200), and duodenal ulcer (10%, 20/200). While only one of the five atrophic gastritis patients was positive for *H. pylori* infection, 52% (68/132), 63% (27/43), and 75% (15/20) of patients with superficial gastritis, gastric ulcer, and duodenal ulcer, respectively, were positive for *H. pylori* infection. The total *H. pylori* infection rate was 55.5% (111/200) (Table 1). This distribution pattern of *H. pylori* infection is similar to other studies in China [46].

We evaluated *H. pylori* virulence with CagA IgG and VacA ELISA on 82 of 111 patient sera. We found that 5.8% of patients (n = 48) were negative for both CagA and VacA (CagA-/VacA-), 9.7% (n = 8) were CagA-/VacA+, 13.4% (n = 11) were CagA+/VacA-, and 18.3% (n = 15) were double positive (CagA+/VacA+). The CagA IgG+ rate in our study was also similar to other studies conducted in China [47].

**Detection of Pro-Oxidant Gene Expression by qPCR**

NOX2 protein is highly expressed in the neutrophils and macrophages, which are recruited into the inflammatory sites by *H. pylori* infection [48]. The NOX2 mRNA level is twofold higher in the gastric mucosa of Hp+ patients than in Hp− patients, and no difference is found among the infected groups stratified with CagA and VacA status (Fig. 2a and Supplementary Figure 1A).

Because DUOX2 protected against *Helicobacter felis* infection in mouse stomach [40], we analyzed DUOX2 mRNA levels in our patients. Unexpectedly, the DUOX2 mRNA levels were significantly higher in Hp− patients compared to Hp+ patients (P = 0.002).
RNA level is decreased in the gastric mucosa of patients who are infected with the \textit{H. pylori} expressing either of the virulence factors compared to Hp- patients without either virulence factors and in Hp- patients (Fig. 2b and Supplementary Figure 1A). The DUOX2 mRNA level of the CagA- or VacA- group is similar to that in the Hp- group. Because DUOX2 and LPO have been postulated to form a defense mechanism against bacterial infection and LPO is expressed in the intestine [22, 34], we also analyzed LPO gene expression in the gastric mucosa. No LPO mRNA can be detected in both Hp- and Hp- patients (\(n = 20\) for each group; data not shown). Furthermore, because NOX1 plays a role in wound-healing [49] and promotes inflammation in a mouse model of ileocolitis [24], we also analyzed NOX1 mRNA levels in the gastric mucosa. Similar to LPO, no NOX1 mRNA was detected in the gastric mucosa (\(n = 20\) for each Hp+ and Hp- groups, as well as two IM samples (data not shown).

**Detection of DUOX, NOX2, and MPO Protein Expression**

We quantified DUOX protein levels with Western blotting (Fig. 3a, b). Consistent with DUOX2 mRNA levels, twofold higher DUOX protein level was present in Hp- gastric mucosa than Hp+ samples. After confirming the Ab specificity by IHC of thyroid tissues (data not shown), this antibody was used to compare DUOX2 protein levels in the gastric mucosa among the Hp- subgroups and Hp- group by IHC. A stronger DUOX staining was detected in Hp- patients especially at the apical surface, although it is also present in the cytoplasm of the epithelial cells (Fig. 3c). Consistent with DUOX2 mRNA levels, mucosa of CagA- or VacA- group had weaker DUOX2 staining than the CagA-/VacA- and Hp- groups (Table 4). Also, the CagA-/VacA- group had similar DUOX2 staining intensity as the Hp- group.

NOX2 IHC was performed on the gastric mucosa of Hp+ and Hp- groups of patients (\(n = 20\) for each group, Fig. 3d). In the Hp+ groups of patients, a stronger NOX2 staining was detected in the infiltrating inflammatory cells compared to that in Hp- gastric mucosa (IHC scores not shown). Similarly to NOX2 IHC pattern, a higher level of MPO+ inflammatory cells is detected in the Hp+ groups than in the Hp- patients (\(n = 15\) for each group, data not shown).
In this study, we found that the gastric mucosa of patients infected with *H. pylori* expressing either CagA or VacA had a lower level of DUOX2 expression than patients infected with CagA−/VacA− *H. pylori* and uninfected patients. This result suggests that the virulence factors in *H. pylori* are able to suppress DUOX2 expression.

*Helicobacter pylori* can survive in the host by defying the host innate and adaptive immune systems [12, 50]. CagA and VacA are known virulence factors that allow *H. pylori* to evade the host immune system. The downregulation of DUOX2 expression by these virulence factors could be a mechanism by which *H. pylori* maintains its presence in the host environment.

**Discussion**

In this study, we found that the gastric mucosa of patients infected with *H. pylori* expressing either CagA+ or VacA+ had a lower level of DUOX2 expression than patients infected with CagA−/VacA− *H. pylori* and uninfected patients. This result suggests that the virulence factors in *H. pylori* are able to suppress DUOX2 expression. *Helicobacter pylori* can survive in the host by defying the host innate and adaptive immune systems that it triggers [12, 50]. CagA and VacA are known virulence factors that allow *H. pylori* to evade the host immune system. The downregulation of DUOX2 expression by these virulence factors could be a mechanism by which *H. pylori* maintains its presence in the host environment.
VacA promote mucosal inflammation through their multifactorial functions, such as induction of pro-inflammatory cytokines, disruption of cell conjunction regulation of host immunity, activation of proliferation and apoptosis [12]. These two virulence factors can manipulate and inhibit human T cells [11]. CagA mediates H. pylori colonization on the apical surface of gastric epithelium by manipulating host’s immune response to allow its persistence in the host [20]. The intracellular CagA forms a complex with the oncogenic c-Met to stimulate cell proliferation [18]. Since DUOX2 is expressed in the mature epithelium [29], and an in vitro study has shown that H. pylori infection induces oxidative stress-associated cell death leading to loss of DUOX2-expressing gastric epithelial cells [51], these may explain why the epithelial cells from CagA+ or VagA+ patients have lower DUOX2 expression. Alternatively, the decrease in DUOX2 expression in the gastric mucosa of Hp+ patients may be a part of the strategy of H. pylori to evade host’s innate immune response [30, 31]. The exact mechanism for H. pylori to suppress DUOX2 expression needs to be further investigated.

Clearly, our finding is different from the animal studies. Grasberger et al. [40] reported that DUOX2 protected mouse stomach from H. felis infection and colonization, and Hornsby et al. found that H. pylori infection induced DUOX2 mRNA expression in the stomach of rhesus macaques [41]. Although H. felis can infect human stomach, it does not cause gastric pathology [52]. It is possible that H. felis induces a different response in mice compared to human’s response to H. pylori. After the rhesus macaques infected with Cag-PAI-positive H. pylori, the DUOX2 mRNA levels were elevated at weeks 4 and 8 and decreased at week 13. This result suggests that H. pylori induce DUOX2 expression temporarily; after the initial induction, the H. pylori-infected cells may progress to adapting the infection. It is possible that the long-term infected patients had a different response from that in the newly infected animals.

H. pylori-infected human gastric epithelial cells recruited inflammatory cells, including neutrophils and macrophages, which induced bactericidal ROS, most notably from NOX2 [53–56]. Helicobacter pylori encodes an array of antioxidant enzymes, including catalase, superoxide dismutase, and a unique bacterial peroxiredoxin, to reduce ROS and escape from ROS-mediated injury [57, 58]. Other studies suggest that H. pylori infection activates NOX2 activity to launch inflammatory responses but fails to eradicate bacterial colonization [59, 60]. Although the virulence factors affected the severity of inflammation, in which CagA+/VagA+-infected patients had more severe inflammation than other subgroups, these factors did not further enhance NOX2 gene expression. Our result supports the view that H. pylori infection activates NOX2 gene expression. The NOX2 gene induction may occur in macrophages rather than neutrophils. The mature neutrophils have few mRNA, and NOX2 protein is synthesized and stored in the granules. Upon stimulation, the mature neutrophils are recruited to the inflammatory site without the need for de novo synthesis of proteins [61, 62]. MPO is a marker for neutrophils and monocytes [24]. A similar pattern of NOX2 and MPO protein expression suggests that either NOX2 or MPO is a good marker for infiltrating inflammatory cells.

DUOX2 has been proposed to defend against bacterial infection by teaming up with LPO and SCN. Although we did not detect LPO mRNA in gastric mucosa, because LPO is highly expressed in the salivary gland, it is possible that LPO can be ingested into the stomach to form a DUOX–LPO–SCN antimicrobial defense network as in the airway and the lower intestine [22, 30]. NOX1 is highly expressed in normal colon but not detectable in normal stomach [26, 27, 55]. A few studies showed that NOX1 was present in gastric cancer [63], and its transcript was detected in H. pylori-associated gastric diseases [64]. In our hands, NOX1 mRNA is not detectable in the gastric epithelium regardless of H. pylori infection status and existing intestinal metaplasia.

In this study, we demonstrated the presence of DUOX2 in the human gastric mucosa. Unexpectedly, the levels of DUOX2 expressed in the gastric mucosa of patients infected with VacA+ or CagA+ H. pylori were lower than patients infected with VacA−/CagA− H. pylori and uninfected patients. This result suggests that VacA or CagA of H. pylori can modulate DUOX2 gene expression in gastric epithelial cells to promote its own survival. How VacA and CagA can affect DUOX2 gene expression is worthy of further studies.

Acknowledgments We thank Dr. Ran Qi, Yonggan Fan, Xianli Liu, and Wenzhao Zhao for their help to this study. This study was supported by a Grant (No. 81370487 to Q.Gao) from National Natural Science Foundation of China.
