We show both experimentally and theoretically the evanescent behaviour of modes in the Band Gap (BG) of finite Phononic Crystal (PC). Based on experimental and numerical data we obtain the imaginary part of the wave vector in good agreement with the complex band structures obtained by the Extended Plane Wave Expansion (EPWE). The calculated and measured acoustic field of a localized mode out of the point defect inside the PC presents also evanescent behaviour. The correct understanding of evanescent modes is fundamental for designing narrow filters and wave guides based on Phononic Crystals with defects.

Keywords: Phononic Crystals, Evanescent modes, Defect modes, Trapping waves, Complex band structures

During the past few years, there has been a great deal of interest in studying propagation of waves inside periodic structures. These systems are composites made of inhomogeneous distribution of some material periodically embedded in other with different physical properties. Phononic crystals (PC) are one of the examples of these systems. PC are the extension of the so-called Photonic crystals when elastic and acoustic waves propagate in periodic structures made of materials with different elastic properties. When one of these elastic materials is a fluid medium, then PC are called Sonic Crystals (SC).

For these artificial materials, both theoretical and experimental results have shown several interesting physical properties. In the homogenization limit, it is possible to design acoustic metamaterials that can be used to build refractive devices. In the range of wavelengths similar to the periodicity of the PC (λ ≃ a), multiple scattering processes inside the PC leads to the phenomenon of so called Band Gaps (BG), which are required for filtering sound, trapping sound in defects, and for acoustic wave guiding.

Propagating waves inside a periodic media are a set of solutions of the wave equations satisfying the translational symmetry property. However, periodic media with point defects where the translational symmetry is broken, or finite periodic media, can support evanescent modes as well. Recently Laude et al. have analyzed the evanescent Bloch waves and the complex band structure of PC. Complex band structures show bands that are simply not revealed by the traditional ω(k) method. By means of the complex band structures, BG can be defined as ranges of frequencies where all Bloch waves must be evanescent.

The goal of the paper is to characterize the evanescent behaviour of waves with frequencies in the BG inside of PC. Analytical, numerical and experimental data show the evidences for the exponential-like decay of these modes. Engelen et al. shown that modes inside BG in photonic crystals decay multiexponentially. Supercell approximation in Extended Plane Wave Expansion (EPWE) has been used in the present work to determine the imaginary part of the wave vector of evanescent modes. Specifically, we have deduced both analytically and experimentally the imaginary part of the wave vector observing that only the first harmonic contributes substantially to the decay of the acoustic field inside complete SC. In all cases we have obtained a very good agreement between theoretical and experimental results.

We have performed experiments in an echo-free chamber of dimensions 8×6×3m³. The finite 2D SC used in this paper forms a square array with lattice constant a = 22cm. The size of the SC is 5a×5a and the radius of the cylinders is r = 10cm. A prepolarized free-field 1/2" microphone Type 4189 B&K has been used throughout the experiments. The diameter of the microphone is 1.32cm, which is approximately 0.06a. Our system 3DReAMS (3D Robotized e-Acoustic Measurement System) is capable of sweeping the microphone through a 3D grid of measuring points located at any trajectory inside the echo-free chamber. Motion of the robot is controlled by NI-PCI 7334.

Figure 1 shows the complex and real band structures for the SC with a point defect. The complex band structures and the value of the k number for the modes inside the BG can be obtained by EPWE and it becomes in a purely real value for the localized mode. We can observe the localized mode at 920Hz (green continuous line). That value exactly coincides with the value obtained by Plane Wave Expansion (PWE) with supercell approximation. We have compared these results with experimental data measuring the Insertion Loss (IL) behind
We can observe that the experimental IL for the localized frequency 920 Hz (blue line) is lower than the experimental IL of a SC with a point defect (blue line). The inset shows the supercell used in the calculations. Red Square marks the value of the imaginary part of the wave vector $Im(k) = -5.6$. 

b) Band structures for a complete SC made of PVC cylinders with $\rho = 0.1$m, $\rho_{PVC} = 1400$kg/m$^3$ and $c_{PVC} = 2380$m/s, embedded in air, $\rho_{air} = 1.23$kg/m$^3$ and $c_{air} = 340$m/s.

In order to study this behaviour of the localized mode we have analyzed numerically the acoustic field inside the SC. In Figures 2a and 2b, we can observe the maps obtained by Finite Element Method (FEM) for the complete SC and for the SC with a point defect respectively.

In Figure 2c, we can observe that the experimental IL for the localized mode at frequency 920 Hz (blue line) is lower than the case of the complete SC (red line), i.e., it can be concluded that there is a passing mode. This results because the localized mode is not killed completely by the SC around the point defect (see also 12). In fact, although the localized mode has an evanescent behaviour, as we will see later, in this case there is not enough number of rows around the point defect to kill it.

For frequencies in the BG, the borders of the point defect act as perfect mirrors producing the localization in this cavity. The localized mode sees a complete SC around the point defect (see also 12). the sound inside a bigger SC with a point defect (see inset of Figure 3a). Figure 3h presents both numerical (blue line) and experimental (blue open circles) values of the acoustic field from the end of the cavity to the end of a SC showing the evanescent behaviour of the localized mode out of the cavity. Analogously as the case of complete SC, here we have also chosen the points with maximum values (see black open circles in Figure 3h) in order to fit an exponential decay ae^bz. The values of the parameters in the fit are a = 3.84±0.92 and b = Im(k) = −5.81± 0.06m⁻¹ and the curve is also plotted in Figure 3h with red dashed line. From the experimental point of view we are constrained by the size of the SC, and as a consequence we have only been able to use a few points for the exponential fit. This results in a big error in the parameters of the fit. Even so, the value obtained for the Im(k) is very closed to the one obtained both analytically (EPWE) and experimentally for the complete SC. The difference is less than 4% in both cases.

We have analyzed one frequency (920Hz) inside the BG, but this exponential-like decay should be observed for every the frequencies inside BG independently if there is or not a point defect in the SC. Figures 3b and 3c represent the experimental 3D spectra for both complete SC and SC with a point defect respectively, in the range of frequencies [750, 1000]Hz, in the BG. In Figure 3b we observe the experimental evidences of the evanescent behaviour for all the modes inside the BG for a complete SC. For the case of the SC with a point defect there is a change in the propagation properties. We observe clearly in Figure 3c: the evanescent behaviour of the localized frequencies out of the region of the point defect and how the localization is produced, showing the effect of the cavity. We can also observe in Figure 3c: the evanescent behaviour for all modes out of the frequencies of the localization range.

The propagation of waves inside periodic structures consists on both propagating and evanescent modes. Using EPWE we have observed the evanescent nature of the modes inside the BG with negative complex Bloch vectors. From the experimental point of view we have observed that the exponential-like decay is dominated by the first harmonic of the Fourier expansion of the Bloch wave, obtaining this exponential-like decay for the modes in the BG (Im(k) = −5.6 ± 1.45m⁻¹ for 920Hz) and for localized modes in a SC with a point defect (Im(k) = −5.81± 0.06m⁻¹). From analytical and experimental data we can conclude that localized modes present evanescent behaviour out of the cavity with the same exponential-like decay than a wave with the same frequency impinging over a complete SC. Due to the breaking periodicity, the physical situations are very different between complete SC and SC with point defects, even so we can conclude that the space observed by the localized wave from inside of the cavity is topologically equivalent to the observed by the same wave from outside of a complete SC. This work is fundamental for the correct understanding of the design of narrow filters and wave guides based on Phononic Crystals with point defects.
