GENETIC VARIATION AT MICROSATELLITE LOCI IN THE TROPICAL
HERB APHELANDRA AURANTIACA (ACANTHACEAE)1

• Premise of the study: To assess the effect of forest fragmentation on genetic variation and population structure of Apelhandra aurantiaca (Acanthaceae), a tropical and ornamental herbaceous perennial plant, we developed the first microsatellite primers for the species.
• Methods and Results: Fourteen microsatellite markers were isolated and characterized from A. aurantiaca genomic libraries enriched for di-, tri-, and tetranucleotide repeat motifs. Polymorphism was evaluated in 107 individuals from four natural populations. Twelve out of 14 genetic markers were polymorphic. The number of alleles per locus ranged from two to 12, and the observed and expected heterozygosities ranged from 0.22 to 0.96 and from 0.20 to 0.87, respectively. Fixation indices ranged from −0.41 to 0.44.
• Conclusions: These newly developed microsatellite markers for A. aurantiaca will be useful for future population genetic studies, specifically to detect the possible loss of genetic diversity due to habitat fragmentation.

Key words: Acanthaceae; Aphelandra aurantiaca; gene flow; genetic structure; Los Tuxtlas tropical rainforest; outcrossing rate.

Aphelandra R. Br. is one of the largest genera of Acanthaceae, comprising ca. 175 species of perennial herbs, shrubs, and small trees restricted to the Neotropics (Wasshausen, 1975; Daniel, 1991). Species in this genus have colored flowering spikes (Wasshausen, 1975), and the genus is well known to horticulturists because some species are cultivated for ornamental purposes (Daniel, 1991). However, until now, no studies of molecular genetic diversity in this genus have been carried out. We focus on the understory herb A. aurantiaca (Scheidw.) Lindl., distributed from southern Mexico through Central and South America (Daniel, 1991). In Mexico, its distribution is restricted to regions with abundant rainfall such as Los Tuxtlas rainforest (Daniel, 1991), where it is one of the dominant understory species (Calvo-Irabin, 1997). The region of Los Tuxtlas, considered the northernmost limit of rainforests in the Americas, has been heavily impacted by deforestation and fragmentation (Dirzo and Miranda, 1991; Dirzo and García, 1992). Because fragmentation produces isolation between populations, it could impact their genetic structure (Chávez-Pesqueira et al., 2014), reducing genetic variation and gene flow, and increasing genetic divergence and inbreeding (Young et al., 1996). Aphelandra aurantiaca is a suitable model to study the genetic consequences of rainforest fragmentation due to the life history characteristics of the species. For example, it has a relatively short life span, which means that some generations have passed since the onset of fragmentation, and it depends on canopy cover, which is usually reduced in forest fragments. Furthermore, because A. aurantiaca’s attractive, nectar-producing flowers are pollinated by birds (Calvo-Irabin, 1997), its mating system can be affected by habitat fragmentation if this reduces species richness and abundance of pollinators (Aguilar et al., 2006). To date, little is known about its genetic structure, particularly in the context of rainforest fragmentation. Therefore, we aimed to develop variable genetic markers to elucidate the genetic diversity and structure of A. aurantiaca.

METHODS AND RESULTS

Using the DNeasy Plant Mini Kit (QIAGEN, Valencia, California, USA), we extracted genomic DNA from a single individual of A. aurantiaca for use in the isolation of microsatellite loci. A paired-end library was prepared by shearing 1 μg of genomic DNA following the standard protocol of the Illumina TruSeq DNA Library Kit (Illumina, San Diego, California, USA). Illumina sequencing was conducted on the HiSeq (Illumina) with 100-bp paired-end reads. Ten million of the resulting sequences were analyzed with the program PAL_FINDR_v.0.2.03 (Castoe et al., 2012), extracting positive reads that contained di-, tri-, tetra-, penta-, and hexanucleotide microsatellites and sending to the program Primer3 (version 2.0.0; Rozen and Skaltsky, 1999) for primer design. To avoid duplicated loci, data were filtered and only primers that occurred one or two times were included; 24 loci out of 1722 that met this criterion were chosen. Primer pairs were tested for amplification and polymorphism using DNA obtained from five different individuals from the four Los Tuxtlas.
populations sampled (Appendix 1), and amplified PCR products were then separated on 4% Metaphor agarose gels (Lonza, Rockland, Maine, USA). After excluding loci that did not amplify, we selected 14 potential polymorphic loci and marked these with fluorescent labels (Table 1). The PCR amplification was carried out in a 20 µL reaction containing 2 µL of 10x PCR buffer (KCI 500 mM, Tris-HCL pH 8.3, gelatin 100 µg/mL, 1% triton, bovine serum albumin [BSA] 1.5 mg/mL), 1 µL of MgCl2 (30 mM), 2 µL of dNTPs (0.2 mM), 2 µL of DNA, 0.5 µL of each of the two primers (10 mM), 0.5 µL of Taq DNA polymerase (5 U/µL), and 12 µL of water (BIOTECMOL, Mexico City, Mexico), performed on a Thermo Scientific Hybaid P2 thermal cycler (Thermo Scientific, Waltham, Massachusetts, USA) using the following conditions: 94°C for 10 min; followed by 35 cycles of 94°C for 1 min, at temperatures between 55–61°C for 1 min, and 72°C for 1 min; and a final extension step of 72°C for 7 min.

To encompass the most genetic diversity of A. aurantiaca in the Los Tuxtlas rainforest, we collected leaf tissue of 107 individuals from four populations (Appendix 1). Genomic DNA was extracted following the cetyltrimethylammonium bromide (CTAB) MiniPrep protocol (Doyle and Doyle, 1987). We selected a subset of loci to function well together in four multiplex reactions (QIAGEN Multiplex PCR Kit) with labeled primers (Applied Biosystems, Foster City, California, USA) (Table 1). Each multiplex PCR mixture (10 µL) contained 2 µL of DNA template (20 ng), 0.2 µL of each fluorescent-labeled forward primer (0.2 µM), 0.2 µL of each reverse primer (0.2 µM), 5 µL of QIAGEN Reaction Mix (1×), and 2.6 µL of water. One or two microliters of these PCR products were diluted in 10 µL of water. One or two microliters of these PCR products (20–50 ng) were run on ABI Prism 310 and ABI 3730xl (Applied Biosystems) automated capillary sequencers; allele sizes were scored manually using GeneScan 500 LIZ Size Standard (Applied Biosystems) in GeneMarker version 2.4.0 (SoftGenetics LLC, State College, Pennsylvania, USA). Of the 14 primers tested, 12 were polymorphic and two were monomorphic with high-quality amplification (Table 2). For each polymorphic loci, we calculated the number of alleles (A), observed heterozygosity (H_o), and expected heterozygosity (H_e; tests of deviations from Hardy–Weinberg equilibrium (HWE) and linkage disequilibrium (LD) were performed using the software Arlequin version 3.5.1.3 (Excoffier and Lischer, 2010). Fixation indices (F_stats) were estimated by GenAIEx version 6.5 (Peakall and Smouse, 2006). The probability of null alleles was estimated using MICRO-CHECKER software (van Oosterhout et al., 2004). We detected higher probabilities of null alleles between two loci (5250 and 1071) as suggested by the general excess of homozygotes (Table 2). There was LD at 10 of 90 paired loci comparisons, and significant departure from HWE was inferred at six loci, although this figure varied depending on the studied population (Table 2). A ranged from two to 12 across the studied populations. H_o and H_e ranged from 0.22 to 0.96 and from 0.20 to 0.87, respectively, and F_stats ranged from −0.41 to 0.44.

CONCLUSIONS

We developed and characterized 12 polymorphic and two monomorphic novel microsatellite markers for the herb A. aurantiaca. The primers will be useful for assessing population genetic structure and mating system of A. aurantiaca in both
