ABSTRACT

Tracheomalacia (TM) is a structural abnormality of the tracheal cartilage causing collapse of its walls and airway obstruction. We describe herein a 4 month-old case of TM associated with operated esophageal atresia with tracheoesophageal fistula. Intraoperative flexible bronchoscope was performed for diagnosis for TM during aortopexy operation via partial sternotomy.

Key Words: Tracheomalacia, flexible bronchoscope, esophageal atresia, aortopexy.

INTRODUCTION

Tracheomalacia (TM) is a located or generalized weakness of the tracheal wall resulting in anteroposterior collapse during expiration or coughing. It is most frequently associated with esophageal atresia (EA) with tracheoesophageal fistula (TOF) (1,2). This 4-month-old infant was the first case of successful aortopexy and using flexible bronchoscope via partial sternotomy (PS) and for TM in Turkey.

CASE REPORT

A 4-month-old male baby was operated our pediatric surgical clinic at first day of age for EA +TOF repair and multiple trials to extubate the child failed and became ventilator dependent. Computed tomographic scan of the thorax showed lower trachea above the carina was obliterated. We were decided to perform flexible bronchoscopy (FB) after weaning in the operation theater for dynamic assessment of TM. Oxygen was connected to the FB.
The tracheal tube was then withdrawn over the bronchoscope to allow for assessment of trachea. The anterior tracheal wall near carina was seen to collapse with exhalation (Video 1). FB revealed significant TM. The tracheal tube was reinserted and aortopexy was performed via partial sternotomy (PS) technique. A final evaluation of the airway was made by FB for the control of the adequacy of aortopexy. Trachea was seen not to collapse (Video 2). He was extubated first post-operative day. There was no problem in 3 months follow-up period.

**DISCUSSION**

In the literature, more than 90% of children with EA and TOF have some form of tracheomalacia (TM) of which 2–25% require aortopexy (3). The airway collapse may be attributable to congenital weakness and malformation of the cartilage rings causing anterior collapse, and with increase in the length of the posterior membranous muscle contributing to posterior airway intrusion. There was a decrease in the normal 4.5:1 circumference ratio of cartilage to membranous trachea and loss of normal “C” shape of the cartilages into more “U” shaped (4). Dilated upper esophageal pouch compressed the trachea in utero and altered its normal development (5).

Contrast-enhanced multidetector computed tomography can provide accurate axial, as well as reconstructions showing two and three-dimensional imaging of airway (4). Direct visual examination and dynamic assessment of the airway with FB has the advantages of detecting TM located in the upper one-third of trachea with improved diagnostic accuracy and identifying vocal cord dysfunction, laryngeal clefts and TEF. Additionally, FB results in less mechanical distortion of the airway than rigid bronchoscopy or endotracheal intubation (2, 4, 6).

If symptoms are serious, TM is treated surgically. The most common surgical treatment method is aortopexy where the shared fascial investments of trachea and aorta and great vessels are utilised by transposing the aorta anteriorly to open and stabilize the trachea (6, 7). Aortopexy was first published by Köylüoğlu et al. in Turkey. But they were performed pericardial flap aortopexy (8). Our aortopexy case is first done via PS technique for ventilator dependent infant in Turkey. In addition, PS is performed in the supine position. It allows direct visualization of the aorta, more accurate placement and directional pull of the sutures can be made with more effective elevation (7).

Tracheomalacia is diagnosed in all patients breathing spontaneously by means of flexible bronchoscopy and it shows the adequacy of the aortopexy or distortion of the trachea during intraoperative period.
