Abstract

Diversity and community patterns of macro- and megafauna were compared on the Canadian Beaufort shelf and slope. Faunal sampling collected 247 taxa from 48 stations with box core and trawl gear over the summers of 2009–2011 between 50 and 1,000 m in depth. Of the 80 macrofaunal and 167 megafaunal taxa, 23% were unique, present at only one station. Rare taxa were found to increase proportional to total taxa richness and differ between the shelf (< 100 m) where they tended to be sparse and the slope where they were relatively abundant. The macrofauna principally comprised polychaetes with nephthyid polychaetes dominant on the shelf and maldanid polychaetes (up to 92% in relative abundance/station) dominant on the slope. The megafauna principally comprised echinoderms with Ophiocen sp. (up to 90% in relative abundance/station) dominant on the shelf and Ophiopleura sp. dominant on the slope. Macro- and megafauna had divergent patterns of abundance, taxa richness (α diversity) and β diversity. A greater degree of macrofaunal than megafaunal variation in abundance, richness and β diversity was explained by confounding factors: location (east-west), sampling year and the timing of sampling with respect to sea-ice conditions. Change in megafaunal abundance, richness and β diversity was greatest across the depth gradient, with total abundance and richness elevated on the shelf compared to the slope. We conclude that megafaunal slope taxa were differentiated from shelf taxa, as faunal replacement not nestedness appears to be the main driver of megafaunal β diversity across the depth gradient.

Introduction

In the Arctic, the pace of climate warming is accelerated, compared to other regions [1], exposing areas like the Canadian Beaufort Shelf to new pressures such as shipping traffic, exotic species, oil and gas extraction and possibly commercial fishing. Arctic marine benthos, which provide key ecosystem functions such as nutrient cycling, organic matter transport, sediment mixing and metabolization of pollutants [2] will likely be influenced by many of the direct and indirect effects of climatic driven changes [3].

The effect of a longer ice-free season on the benthos is currently under debate [4,5]. Thinning and reduced ice conditions accompanied by upwelling favourable winds [6] may increase primary productivity and the benthic standing stock [7–9]. Alternatively, the loss of sinking ice-algae and a shift toward open-water primary productivity may lead to a zooplankton-dominated ecosystem and a decrease of food supply for the benthos [10,11]. In addition, warming Arctic seas may facilitate changes in benthic community structure through the introduction of lower latitude taxa [11–13]. Hence, the fate of Arctic shelf benthos and the tightly coupled pelagic environment [14] in a continuing climate warming scenario remains unclear. Recently, a renewed interest in industrial exploration of the Canadian Beaufort Sea has prompted a resurgence of benthic surveys providing a baseline for which to monitor future change. Understanding regional spatial patterns and drivers of benthic abundance and diversity is needed to effectively monitor potential human induced shifts [3].

On continental margins benthic patterns principally vary across the depth gradient [15]. There is wide acceptance that continental shelf benthos decrease in abundance with increasing depth [16] as a result of decreases in the flux of particulate organic carbon on which they rely [17,18]. Patterns of benthic taxa richness across depth gradients are less consistent [19,20], although theory predicts a unimodal distribution with peak diversity occurring at mid-slope where shallow and deep-sea species ranges overlap [15,21]. In the Arctic, macro- and megafaunal abundance and
taxa richness are observed to decrease monotonically with depth from mid-shelf to slope [14,22,23] as does the flux of particulate organic matter [24]. However, few marine studies have examined the contribution of rare species to local species richness [25,26] and how the distribution of rare species may vary with depth. Factors that affect the distribution of rare species may be important for monitoring and conservation, as rare species are theorized to buffer against alterations in ecosystem function under environmental change, even those functionally similar to dominants [26–28].

Benthic community composition also varies across the depth gradient. Previous work in the Canadian Beaufort has shown macrofauna composition to be similar at corresponding depths along the shelf [23]. This observation is consistent with the expectation of faunal replacement ($\beta$ diversity) across the bathymetric gradient, largely in response to decreased food availability [17]. However, Arctic benthos have been predicted to have larger depth ranges and thus display a slower rate of faunal replacement across depth gradients [17]. On the pan-Arctic scale, there is evidence of large overlap between shelf and slope taxa, suggesting that many taxa may be eurybathic [22,30] and that the shelf benthos is simply a nested sub-assemblage of shelf benthos rather than being a community that replaces the shelf fauna as depth increases or food supply diminishes. The distinction between spatial replacement and nested structure may be important to understanding how present day food availability is determining faunal distribution patterns and the response of benthos to predicted changes in future food availability. Furthermore, several studies have demonstrated that $\beta$ diversity (faunal replacement) can vary between faunal groups [31–34], likely due to differences in metabolism, trophic structure, mobility and dispersal [15]. The degree to which the rate of faunal replacement differs between Arctic macro- and megafauna has yet to be quantified.

To inform future monitoring programs on the Canadian Beaufort Shelf we compared macro- and megafaunal patterns of rarity, abundance and community composition. Specifically our objectives were to determine: 1) what factors co-vary with the distribution of rare taxa, and the similarity of macro- and megafaunal patterns of 2) abundance and taxa richness ($\alpha$ diversity) and 3) $\beta$ diversity.

**Methods**

**Study Area**

The Canadian Beaufort Shelf is a long and narrow (450 km by 130 km) Arctic shelf covering approximately 64,000 km$^2$ (Figure 1). Both the shelf and adjoining slope study areas are bounded by the Mackenzie Trough to the west, the Mackenzie Delta to the south and the Amundsen Gulf to the east. The slope begins between the 80 m and 200 m isobaths [35,36]. Within the spatial extent of this study area (shown by the dotted black line in Figure 1) the shelf break was located at 100 meters in depth. The shelf break was defined as the depth at which the rate of change of the average slope, modelled by the logistic function: $f(x) = a/(1 + b e^{-cx})$ where $x =$ depth, was the greatest. The continental slope gradually drops in depth at an angle of 1° to 2° between the shelf break and 1000 m. Within the study area, the depth range of the shelf is 50 m (50 – 100 m) and depth range of the slope is 900 m (100 – 1,000 m).

The dominant bottom current moves water of both Pacific (surface) and Atlantic (>200 m) [9,37] origin eastward along the shelf and slope [35,36]. Upwelling can occur all along the shelf break bringing nutrient rich water onto the shelf [38]. Several features enhance upwelling of deep water on the Beaufort Shelf: the wide and deep Mackenzie Trough [39], the narrow and stable Kugmallit Valley [38,40] and the near shore steep slope east of Cape Bathurst [41,42].

**Sampling**

Benthic sampling was undertaken through a partnership between ArcticNet (www.arcticnet.ulaval.ca), British Petroleum, Imperial Oil and the Canadian Healthy Oceans Network [43] to gather baseline benthic data in the oil and gas exploration lease areas of the Beaufort shelf and slope. Samples were collected within a 12,000 square kilometre spatial extent, northeast of the Mackenzie Trough (Figure 1). Sampling occurred during three summer expeditions on the CCGS Amundsen during the 2009, 2010 and 2011 ArcticNet field programs. Data from 48 sampling stations within Imperial Oil’s and British Petroleum’s exploration license areas (Ajurak, Pokak, EL451 and EL453) were utilized in this study.

At each sampling station, macrofauna were sampled using a 0.25 m$^2$ USNEL box corer and megafauna were sampled with an Agassiz trawl (1.5 m in width, 0.7 m in height). On average the 48 paired box core and trawl samples were separated by 770 m (range 45 – 3460 m) in horizontal distance and 7 m (range 0 – 85 m) in depth. Sediment from half of the surface area of the box corer was utilized down to a maximum depth of 15 cm. The surface area sampled was 0.125 m$^2$ and the average volume sampled was 1200 cm$^3$. Macrofauna were collected on a 0.5 mm mesh sieve and fixed in 4% buffered formalin for later identification. Towing speed for trawls ranged from 1.5 to 2 knots and bottom time from 3 to 5 minutes, with the exception of the 2009 trawls where bottom time was 10 minutes. The trawl mesh was 5 mm and samples were sieved with a 2 mm mesh after collection, with the exception of 2009 sampling where a 0.5 mm sieve was used. Faunal densities were standardized to the average trawl area: 450 m$^2$ (trawl net width $\times$ ship speed $\times$ bottom time). Megafauna which could not be confidently identified onboard were preserved in 4% buffered formalin or frozen at −20 Celsius. Megafauna identified onboard were discarded or used for other analyses.

Benthic sampling was not consistent between sampling years; samples were distributed asymmetrically between shelf and slope and with each subsequent year were taken later in the summer season and farther to the east (Figure 1). In addition, sea ice conditions in the Beaufort varied considerably during these years. The sea-ice breakup on the Beaufort shelf was earlier in the year and reached a lower minimum ice coverage in 2010 and 2011 (Figure 1).

**Data preparation and quality control**

All benthic samples were collected, processed and identified to the lowest taxonomic level possible using the same protocol across all sampling years. The metadata can be accessed through the Polar Data Catalogue (www.polardata.ca) and datasets will be publicly accessible through Dryad (datadryad.org). The resulting faunal datasets needed some modifications prior to use in this study, primarily to ensure the consistent use of taxonomic names—in order to prevent the inflation of taxa richness. Both box core and trawl datasets were validated through the removal of synonyms and unaccepted names using the WoRMS (www.marinespecies.org) Taxon Match tool.

Only 46% of box core and 60% of trawl faunal specimens were identified to the species level. The majority of these higher-order identifications were the result of broken or damaged specimens and the lack of taxonomic focus or expertise within certain phyla such as Sipuncula and Nemertea. Excluding all higher-order taxa
to standardize the data to the species level would remove too large
a portion of the total records. Alternatively, specimens consistently
identified to higher-orders (e.g. Nemertea) remained in the
database while specimens identified to several taxonomic ranks
(e.g. Ophiuridae (Family), Ophiuracae (Subfamily), Ophiocen
(Genus), sericeum (species)) were grouped to the family level.
Records were removed from the database only if specimens that
were identified to several taxonomic ranks were ranked higher
than the family level (e.g. Ophiurida (Order)). This system was
employed to balance the retention of detail and the loss of records
from the dataset. The resulting datasets included 73% of box core
records and 92% of trawl records. Grouping organisms identified
to several taxonomic ranks acts as a quality control mechanism by
minimizing any potential interannual variability in taxonomic
identifications. Previous studies have validated a higher-taxon
approach to data quality control by demonstrating that grouping
taxa into higher taxonomic classes has little effect on the detection
of diversity patterns [30,44,45].

The box core and trawl tended to selectively sample macrofa-
una and megafauna, respectively. Seventy-nine taxa (32%) were
sampled by both gear types. However, the shared taxa were not
sampled in a quantitatively comparable way by the two gear types.
The trawl, because of its limited penetration of the sediment and
larger mesh size, would tend to undersample the macrofauna. On
the other hand, the box corer would tend to inaccurately sample
the more widely spaced megafaunal organisms, because of its
relatively small surface area. Two distinct quantitative datasets
were created by removing macrofauna from the trawl samples and
megafauna from the box corer samples. Taxa were identified as
macrofauna or megafauna based on the frequency at which they
were sampled by each gear type, assuming that megafauna were
collected more frequently and effectively by the trawl than by the
box corer and vice versa. The removal of shared taxa resulted in a
40% reduction in box corer taxa and a 30% reduction in trawl
taxa. In addition, meiofauna and colonial fauna were removed
from the datasets; meiofauna are not consistently sampled with
larger mesh sieves and colonial fauna are not suitable for
individual count data.

Analyses
All statistical analyses were completed in the R environment for
statistical computing (www.r-project.org) with aid from commu-

Figure 1. Sampling stations and ice coverage on the Beaufort shelf and slope from 2009 to 2011. One box core and trawl sample were
collected from each station (left panel). Sample sizes were n = 18 in 2009, n = 18 in 2010 and n = 12 in 2011. Black dotted line outlines the spatial
extent of sampling used to calculate the average slope. Ice coverage (white area, right panel) for 2009, 2010 and 2011 benthic sampling periods. Blue
coverage area outlines the area over which ice coverage was calculated. Blue lines in plots represent historic ice coverage (median from 1981 to
2010). Green bars indicate when benthic sampling occurred. Ice coverage data courtesy of Canadian Ice Service, Environment Canada.

Multivariate cluster and ordination techniques were utilized to explore the macro- and megafaunal assemblage patterns. A fourth-root transformation was applied to the matrices to reduce the influence of highly abundant taxa [48]. The Bray-Curtis (BC) dissimilarity measure was computed to obtain an ecologically meaningful distance measure based on the relative abundance and composition of taxa between stations. $\beta$ diversity was computed using BC similarity (BC dissimilarity $-1$). Ward’s method of hierarchical clustering was used to define compact clusters of stations. The number of clusters was determined by selecting the maximum average silhouette width (ASW), a measure of average dissimilarity of stations within versus between clusters [49], for all combinations of cluster sizes. Station dissimilarities were also visualized through non-metric multidimensional scaling (nMDS) ordination. Average relative abundances of taxa, the contribution of each taxa to total abundance, by cluster were used to define dominant taxa representative of clusters.

Results and Discussion

Distribution of occurrence, abundance and rarity

Two hundred and forty-seven taxa were collected at the 48 stations sampled. A total of 4,752 individuals sampled from a 6 m$^2$ area were distributed among 80 macrofauna taxa and a total of 452,115 individuals sampled from a 21,600 m$^2$ area (approx.) were distributed among 167 megafauna taxa. Piepenburg et al. [30] estimated the Beaufort Shelf holds around 1,100 species of major macro- and megafaunal taxa (annelids, arthropods, echinoderms and molluscs), which suggests we have only captured roughly one quarter of the taxa present. Most of the abundance was concentrated in polychaeta (66%), malacostraca (15%) and bivalvia (10%) classes in the macrofauna and ophiuroidea (28%), malacostraca (23%) and asteroidea (13%) classes in the megafauna. Many taxa had very low frequencies of occurrence. The macrofauna had 24 uniques (30%) (taxa present at only one station) and the megafauna had 32 uniques (19%), slightly lower compared to other continental shelves ($\approx 40\%$) [26,50] but similar to other Arctic regions ($20–30\%$) [25,51]. The true percent of uniques may be higher, considering that the number of uniques

![Figure 2. Distribution of occurrence.](image1)

![Figure 3. Proportion of rare taxa unique to or shared between shelf and slope.](image2)
was likely deflated by the grouping of many taxa to the family taxonomic rank.

Beaufort macro- and megafauna displayed the typical right-skewed distribution of occurrence [52], where most taxa are rare and few are widespread (Figure 2A). Rare taxa are defined here as taxa restricted in occurrence (≤ 10% of stations), not necessarily in abundance. A property of this distribution is that rare taxa comprise a larger portion of total taxa richness at the regional scale (all samples) with a ratio of rare to common taxa of 1.3:1 for macrofauna and 1.2:1 for megafauna while at the sample scale common taxa comprise the largest portion of total taxa richness with a ratio of common to rare taxa of 6:1 for macrofauna and 8:1 for megafauna. At all scales, rare taxa comprise a greater proportion of total macrofaunal taxa. However, this may simply be an artifact of differences in sample area. The larger sample area of trawls makes them more likely to collect patchy and sparsely distributed taxa. Previous studies have demonstrated a positive correlation between the presence of rare taxa and depth [51]; however, we found no such relationship when taking into account proportion (data not shown). Rather, we found the number of rare taxa was a function of the total taxa richness (macrofauna: Spearman’s ρ = 0.9, p < 0.001; megafauna: Spearman’s ρ = 0.8, p < 0.001), similar to the findings of Ester and Mullineaux [53]. Additionally, though rarity can be dependent of phyla in terrestrial systems [54,55], we were not able to reject the null hypothesis that rare taxa were distributed with equal proportion among phyla (data not shown).

A positive relationship exists between occupancy and average relative abundance (Figure 2B) for both faunal groups (macrofauna: Spearman’s ρ = 0.6, p < 0.001; megafauna: Spearman’s ρ = 0.5, p < 0.001). As expected, common taxa tended to be higher in local relative abundance than rare taxa which on average contributed less to total abundance per station [56]. However, some rare taxa were relatively abundant at the few stations they were present (ex. macrofauna: *Pseudosphyrapus serratus*, Thyasiridae, *Terebellides*; megafauna: *Apomatus similis*, Pectinidae, *Siphonodentilium*, *Ophiura*). These rare taxa, high in relative abundance, may be habitat specialists dominant in their niche but unable to persist in other habitats [26,57]. Or, their abundance may be the result of a localized disturbance or recruitment event. Alternatively, these taxa may be pseudo-rare: taxa that appear rare because they are...
Patterns in abundance and taxa richness

Total abundance on the Beaufort shelf decreased with depth (Figure 4), confirming Conlan et al.’s [23] result. Megafauna showed a stronger negative correlation between abundance and depth (megafauna: Spearman’s \( r = -0.6, p < 0.001 \); macrofauna: Spearman’s \( r = -0.4, p < 0.05 \)) and had a larger range of abundance values on the shelf than slope (F-test: \( p < 0.05 \)). Yet, no decrease in abundance with depth was observed when the depth range was restricted to the slope between 100 to 1,000 m (macrofauna: Spearman’s \( r = -0.1, p > 0.1 \); megafauna: Spearman’s \( r = -0.2, p > 0.1 \)). Differences between macro- and megafauna in abundance and taxa richness (\( \alpha \) diversity) across the depth gradient are illustrated by grouping shelf and slope stations (Figure 5). Macrofaunal shelf stations showed slightly greater mean abundance and mean richness compared to slope stations, but this difference was not statistically significant (Wilcoxon test: \( p > 0.05 \)). Megafauna were on average significantly more abundant and taxa rich (Wilcoxon test: \( p < 0.001 \)) at shelf stations than at slope stations. Renaud et al. [14] showed similar declines in larger fauna with depth on the Beaufort Shelf. Declines in megafaunal abundance while macrofauna remain relatively constant across the depth range (50 – 1,000 m) supports the notion of increased prevalence of smaller body sizes with depth [16,60–63]. The most parsimonious explanation for the observed shift from larger to smaller size classes with depth is the diminishing supply of organic material [64] as larger fauna require more

energy to survive and reproduce [15,16]. No difference in
taxonomic distinctness was found between shelf and slope for
macro- or megafauna (Wilcoxon test: p > 0.05, data not shown).
Shelf–slope differences are partially confounded by temporal
and spatial variability introduced through the multiple year
sampling scheme, 2009 to 2011. Over this time period, the spatial
extent of sea-ice decreased, sampling was carried out further into
the ice-free season and farther to the east (Figure 1). To illustrate
the potential effects of this temporally associated variability in
macro- and megafaunal abundance and taxa richness, shelf and
slope stations were grouped by sampling year (Figure 5). Variation
in macrofaunal abundance and richness was explained by both
depth and year with year explaining more of the total variance
(Table 1). Macrofaunal mean abundance and richness increased
each year regardless of position on shelf or slope. Variation in
megafaunal abundance and richness was also explained by both
depth and year, however, depth explained more of the total
variation (Table 1). We found a significant interaction between
depth and year which indicates the affect of year on megafaunal
abundance and richness was not consistent across shelf and slope
stations. This interaction may be an artifact of inconsistencies in
trawl sample areas (discussion below) in combination with the lack
of slope stations in 2011.
Spatial location is likely to influence the distribution of
abundance and taxa richness as a high degree of benthic spatial
heterogeneity exists on Arctic shelves [24,65]. In addition, seasonal
and temporal variability of Arctic benthos across multi-year
sampling programs have been found to be insignificant relative to
spatial variability (V. Roy and P. Archambault, unpublished data).
Therefore, the variance explained by sampling year in our analysis
(Table 1) is more likely a result of location. As sampling occurred
farther to the east with each subsequent year, greater macrofaunal
abundance and richness may be a consequence of the proximity to
nutrient rich upwelled water from Cape Bathurst [42].
If the location of sampling was indeed affecting abundance and
richness patterns, why were megafaunal abundance and richness

increased with each sampling year as stations moved eastward along the shelf and slope.

**Patterns in β diversity**

Macro- and megafauna differed in β diversity patterns. Sixty-five percent of macrofaunal and only 46% of megafaunal taxa occurred on both the shelf and slope, not including unicorns. Macrofauna shelf and slope taxa were similar in overlap to that previously observed at the pan-Arctic level (61%) [22,30]. A significant negative correlation between community similarity and depth was only detected in the megafauna (macrofauna: Spearman’s $\rho = -0.2, p_{adj} > 0.05$; megafauna: Spearman’s $\rho = -0.7, p_{adj} < 0.001$, Figure 7), corroborating previous work that established megafauna had a faster rate of species replacement than macrofauna [32]. However, both species replacement and nestedness can drive β-diversity patterns [67]. Nestedness, contrary to species replacement, is caused by species loss without a gain of new species along a gradient [68]. As described in the previous section, total abundance and taxa richness of the megafauna decreased more rapidly with depth. Considering that β diversity is not independent of α diversity [31], megafaunal β diversity could be purely driven by decreased α diversity with depth. Additionally, decreasing richness with depth could indicate that megafaunal β diversity is more likely driven by faunal loss (nestedness) than faunal replacement.

To distinguish between replacement and nestedness drivers of β diversity, stations were clustered based on similarity in composition and relative abundance of taxa (Figure 8). Mean average silhouette widths (ASW), a measure of between versus within cluster variability at a scale from 0 to 1, were low for macrofauna (0.19) and megafauna (0.20) clusters. Low ASW is an indication that clusters represent loose groupings rather than distinct, structured assemblages [69], which fits the established view that faunal change is continuous across the depth gradient lacking distinct zones [15,70]. The spatial distribution of clusters (Figure 9) depicts the bathymetric gradient as the major structuring factor in station clustering. In agreement with the β diversity results, megafaunal clusters were more clearly distributed according to depth. Megafaunal groupings on Arctic shelves have previously been noted to follow depth gradients [71,72], likely shaped by food availability [70,73,74]. Sediment properties were not likely a major cause of the faunal clustering as sediment grain size on the Beaufort Shelf does not vary largely with depth [14], but more so along the east-west axis [75]. Different water masses found on the shelf and slope.

Changes in the dominant macro- and megafaunal taxa between clusters reveal compositional differences (Figure 10A) that provide
evidence of faunal replacement as a main driver of $\beta$ diversity. Dominant taxa were defined as the top four taxa in terms of average relative abundance for each cluster. The dominant taxa typically represented over 50% of the cumulative average relative abundance per cluster (macrofauna: A = 62%, B = 83%, C = 94%, D = 48%; megafauna: A = 63%, B = 52%, C = 52%, D = 57%). Across all clusters, the macrofauna were principally comprised of polychaetes. Macrofaunal cluster A (shelf cluster) was characterized by cirratulid and nephtyid polychaetes and leuconid cumaceans. Macrofaunal cluster D (slope cluster) was characterized by maldanid polychaetes, Sipuncula, thyasirid bivalves and tanaid Pseudosphyrapus serratus. Clusters B and C, also found on the slope but compositionally distinguishable from D cluster macrofauna, may be influenced by smaller scale processes and forces than depth gradients. Cluster B was distinct in having higher relative abundances of polychaetes Capitellidae, Terebellides sp. and Phyllodocidae compared to other slope clusters. Cluster C was distinguished by its extremely high relative abundance of maldanid polychaetes (60% of total abundance on average).

Across all clusters, the megafauna were principally comprised of echinoderms, typical of Arctic shelves [10]. Megafauna shelf cluster A, containing only 2011 stations, was characterized by the ophiuroid Ophiocten sp. as well as polychaete Cistionides sp., amphipod Ampelisca sp. and bivalve Nucula sp.; shelf cluster B, located west of cluster A and Kugmallit Valley, was characterized by isopod Saduria sabini, gastropod Tachyhyphus sp. and holothurian Myriotrochus sp. Megafauna shelf break cluster C was characterized by asteroid Pontaster tenuispinus, astastid bivalves, ophiuroid Ophiocten sp. and polynoid polychaetes. Megafauna slope cluster D was characterized by ophiuroid Ophiopleura sp., asteroid Pontaster tenuispinus and scaphopod Siphonodentalium sp. Some megafauna taxa dominant in shelf clusters were not present on the slope and vice versa (Figure 10B) providing evidence that slope taxa are not just a nested subset of shelf taxa.

Conclusions

The Canadian Beaufort shelf and slope host a diverse assemblage of macro- and megafauna, 247 taxa—many (30%) of which were classed at the family taxonomic rank or higher, indicating species richness may be much greater. At a regional scale, rare taxa constituted the majority of taxa represented while faunal numbers in individual samples were dominated by taxa common throughout the region. We found that the proportion of rare taxa was independent of depth and phylum, instead rarity was simply a function of the total taxa richness—the more taxa present in a sample the greater the number of rare taxa. We hypothesize that rare taxa are driven by different processes on the shelf (sparsity) and slope (pseudo-rarity), since rare taxa on the slope tended to contribute more to local faunal numbers compared to those on the shelf.

Our results indicate that macro- and megafauna have divergent patterns of abundance and $\alpha$ and $\beta$ diversity on the Beaufort shelf and slope. Macrofauna showed greater change in $\beta$ diversity with year and/or location compared to the megafauna, although this relationship was weak for both faunal groups. Megafauna show greater change in abundance, taxa richness and $\beta$ diversity with depth compared to the macrofauna, conceivably owing to a greater cost of the declining food supply for larger bodied organisms. We infer that megafaunal $\beta$ diversity is not merely driven by $\alpha$ diversity, since shifts in dominant taxa are evident between shelf and slope clusters. Furthermore, we deduce that faunal replacement is a greater driver of megafaunal $\beta$ diversity than nestedness as some dominant megafauna in shelf clusters are not present on the slope and vice versa, suggesting that slope taxa
are indeed differentiated from shelf taxa and not solely a nested subset of shelf taxa.

The effect of temporal variability on the benthos is less clear. Sampling year explained a portion of both macro- and megafaunal variability in abundance and richness, however, year effects were highly confounded by location on the shelf and the timing of sampling with respect to sea-ice conditions (with sampling occurring later into the summer season with each year). We speculate that the major source of this temporally associated variability was spatial heterogeneity; however, it may be a combination of several factors such as a longer growing season, temporally variable (spring vs. summer) recruitment events or faster growth with increased primary productivity input to the benthos under reduced ice conditions. The latter would support the notion that the benthic standing stock will increase as sea-ice retreats in the Arctic. Under the alternative scenario, the loss of sinking ice-algae and a shift toward open-water primary productivity leads to a decreased food supply for shelf benthos. If this scenario holds true on the Beaufort shelf, our observations suggest that shelf fauna could become more similar to the present day slope fauna. As slope megafauna are differentiated from shelf fauna and smaller body size organisms (macrofauna) contribute more to total abundance on the slope, this would likely have cascading affects on higher trophic levels [77,78].

As development encroaches and the Beaufort shelf and slope are exposed to pressures from industry and climate warming, further benthic monitoring will be essential to the management of biodiversity and ecosystem services. The establishment of effective long-term monitoring in the region will require a better understanding of larger scale spatial differences along the shelf. Several questions remain for future research: Are bathymetric trends in macro- and megafauna diversity and community structure consistent from east to west along the shelf? How might scale affect the observed spatial patterns? How does the magnitude of spatial variability in faunal abundance compare to temporal and depth related variability? Answering these questions will be crucial to distinguishing long-term changes in the benthos from spatial and interannual variability.

Acknowledgments

We would like to thank the officers and crew of the CCGS Amundsen for their assistance with benthic sampling, as well as scientific crew and technicians for their support on board. Many thanks to Lisa Tread de Coeli, Laure de Montety, Gustavo Yunda and Bernard Boucher for their work in faunal identifications and Marieve Bouchard Marmen, Simon Bourgeois, Mathieu Casson, Cindy Grant, Melanie Lévesque and Laure de Montety for onboard sampling. Thank you to Verena Tumniclíff, Julia Baum and two anonymous reviewers for their insightful comments on the manuscript.

Author Contributions

Conceived and designed the experiments: PA. Analyzed the data: JN SKJ. Contributed reagents/materials/analysis tools: PA. Wrote the paper: JN SKJ PA.
