Efficient stochastic optimisation by unadjusted Langevin Monte Carlo

Application to maximum marginal likelihood and empirical Bayesian estimation

Abstract
Stochastic approximation methods play a central role in maximum likelihood estimation problems involving intractable likelihood functions, such as marginal likelihoods arising in problems with missing or incomplete data, and in parametric empirical Bayesian estimation. Combined with Markov chain Monte Carlo algorithms, these stochastic optimisation methods have been successfully applied to a wide range of problems in science and industry. However, this strategy scales poorly to large problems because of methodological and theoretical difficulties related to using high-dimensional Markov chain Monte Carlo algorithms within a stochastic approximation scheme. This paper proposes to address these difficulties by using unadjusted Langevin algorithms to construct the stochastic approximation. This leads to a highly efficient stochastic optimisation methodology with favourable convergence properties that can be quantified explicitly and easily checked. The proposed methodology is demonstrated with three experiments, including a challenging application to statistical audio analysis and a sparse Bayesian logistic regression with random effects problem.

Keywords Maximum marginal likelihood estimation · Empirical Bayesian inference · Stochastic approximation · Markov chain Monte Carlo methods · Unadjusted Langevin Algorithm · Recursive estimation

1 Introduction

Maximum likelihood estimation (MLE) is central to modern statistical science. It is a cornerstone of frequentist inference (Berger and Casella 2002), and also plays a fundamental role in parametric empirical Bayesian inference (Carlin and Louis 2000; Casella 1985). For simple statistical models, MLE can be performed analytically and exactly. However, for most models, it requires using numerical computation methods, particularly optimisation schemes that iteratively seek to maximise the likelihood function and deliver an approximate solution. Following decades of active research in computational statistics and optimisation, there are now several computationally efficient methods to perform MLE in a wide range of classes of models (Gentle et al. 2012; Boyd and Vandenberghe 2004).

In this paper, we consider MLE in models involving incomplete or “missing” data, such as hidden, latent or unobserved variables. Expectation maximisation (EM) optimisation methods (Dempster et al. 1977) are common strategies to obtain approximate solutions in this setting. However, they rely on a maximization step of a surrogate which is not possible in most models (Robert and Casella 2004). Several strategies can be considered to overcome this issue. In particular, we consider Robbins–Monro stochastic approximation (SA) schemes that use a Monte Carlo stochastic simulation algorithm to approximate the gradients that drive the optimisation procedure (Robbins and Monro 1951; Delyon et al. 1999; Kushner and Yin 2003; Fort et al. 2011). When combined with Markov chain Monte Carlo (MCMC) algorithm, SA schemes provide a powerful general methodology which
is simple to implement, has a detailed convergence theory (Atchadé et al. 2017), and can be easily applied to a wide range of moderately low-dimensional models.

The expectations and demands on SA methods constantly rise as we seek to address larger problems and provide stronger theoretical guarantees on the solutions delivered. Unfortunately, existing SA methodology and theory do not scale well to large problems. The reasons are twofold. First, the family of MCMC kernels driving the SA scheme needs to satisfy uniform geometric ergodicity conditions that are usually difficult to verify for high-dimensional MCMC kernels. Second, the existing theory requires using asymptotically exact MCMC methods. For large models, these are usually high-dimensional Metropolis–Hastings methods such as Hamiltonian Monte Carlo (Girolami and Calderhead 2011; Durmus et al. 2017), which are some-
where \( \tilde{H}_{\theta_n} \) is some estimator of the intractable gradient \( \theta \mapsto \nabla_{\theta} \log p(y|\theta) \) at \( \theta_n \), \( \Pi_{\theta} \) denotes the projection onto \( \Theta \), and \( (\delta_n)_{n\in\mathbb{N}_0} \in (\mathbb{R}^+_+)^{\mathbb{N}} \) is a sequence of stepsizes. From an optimisation viewpoint, iteration (2) is a stochastic generalisation of the projected gradient ascent iteration (Boyd and Vandenberghe 2004) for models with intractable gradients. For \( n \in \mathbb{N} \), Monte Carlo estimators \( \tilde{H}_{\theta_n} \) for \( \nabla_{\theta} \log p(y|\theta) \) at \( \theta_n \) have detailed theory for these algorithms, including explicit and easily verifiable geometric ergodicity conditions (Dumus and Moulines 2017; Dalalyan 2017; Eberle and Majka 2018; De Bortoli and Durmus 2019). This will allow us to design a stochastic optimisation scheme with favourable convergence properties that can be quantified explicitly and easily checked.

### 2.3 Langevin Markov chain Monte Carlo methods

Langevin MCMC schemes to sample from \( p(x|y, \theta) \) are based on stochastic continuous dynamics \( (X^\theta_t)_{t \geq 0} \) for which the target distribution \( p(x|y, \theta) \) is invariant. One fundamental example is the Langevin dynamics solution of the following stochastic differential equation (SDE)

\[
dX^\theta_t = -\nabla_x \log p(X^\theta_t|y, \theta) \, dt + \sqrt{2} dB^\theta_t ,
\]

where \( (B^\theta_t)_{t \geq 0} \) is a standard \( d \)-dimensional Brownian motion. Under mild assumptions on \( p(x|y, \theta) \), this SDE admits a strong solution for which \( p(x|y, \theta) \) is the invariant probability measure. In addition, there are detailed explicit convergence results for \( (X^\theta_t)_{t \geq 0} \) to \( p(x|y, \theta) \) under different metrics (Eberle 2016; Eberle et al. 2017). Note that other SDEs satisfy these favorable properties such as the kinetic Langevin dynamics (Dalalyan and Riou-Durand 2018).

However, sampling solutions for these continuous-time dynamics is not feasible in general. Therefore, discretisations have to be used instead. In this paper, we mainly focus on the Euler-Maruyama discrete-time approximation of (5), known as the Unadjusted Langevin Algorithm (ULA) (Roberts and Tweedie 1996), given by

\[
X_{k+1} = X_k - \gamma \nabla_x \log p(X_k|y, \theta) + \sqrt{2} \gamma Z_{k+1} ,
\]

where \( \gamma > 0 \) is the discretisation step size and \( (Z_k)_{k \in \mathbb{N}_0} \) is a i.i.d. sequence of \( d \)-dimensional zero-mean Gaussian random variables with identity covariance matrix. We will use this Markov kernel to drive our SA schemes.

Observe that (6) does not exactly target \( p(x|y, \theta) \) because of the bias introduced by the discrete-time approximation. Computational statistical methods have traditionally addressed this issue by complementing (6) with a Metropolis–Hastings correction step to asymptotically remove the bias (Roberts and Tweedie 1996). This correction empirically deteriorates the convergence properties of the chain and may
lead to poor non-asymptotic estimation results, particularly in very high-dimensional settings (see for example Durmus et al. 2018). However, until recently it was considered that using (6) without a correction step was too risky. Fortunately, recent works have established detailed theoretical guarantees for (6) that do not require using any correction (Dalalyan 2017; Durmus and Moulines 2017). In addition, new explicit convergence bounds have been derived under various assumptions on the target probability distribution (Dalalyan 2017; Cheng et al. 2018; Cheng and Bartlett 2017; Lee et al. 2018). In addition, accelerations and variations of ULA have been studied, both theoretically and experimentally, yielding better ergodic convergence rates (Maddison et al. 2018; Ma et al. 2019; Muehlebach and Jordan 2019; Dalalyan and Riou-Durand 2018). However, such extensions are out of the scope of the present work whose main contribution is not to provide new results to the existing Markov chain theory but to use the theoretical guarantees of ULA in order to study SA schemes driven by this efficient but inexact sampler.

Note also that the methodology we propose and analyse in this paper is fundamentally different from the Stochastic Gradient Langevin dynamics (Vollmer et al. 2016; Teh et al. 2016; Welling and Teh 2011a; Patterson and Teh 2013; Ahn et al. 2014, 2012) which is an MCMC algorithm to sample from \( p(x|y, \theta) \) using estimators of \( \nabla_x \log p(x|y, \theta) \). Finally, it should be highlighted that, in an independent line of work, a similar methodology is studied under a different set of assumptions in (Karimi et al. 2019).

### 2.4 The SOUL algorithm and main results

We are now ready to present the proposed Stochastic Optimization via Unadjusted Langevin (SOUL) methodology. Let \( (\theta_n)_{n\in\mathbb{N}^+} \subset \mathbb{R}^d \) and \( (m_n)_{n\in\mathbb{N}} \subset \mathbb{N}^\alpha \) be the sequences of Hessians and batch sizes defining the SA scheme (2)–(3). For any \( \theta \in \Theta \) and \( y > 0 \), denote by \( R_{y, \theta} \) the Langevin Markov kernel associated with (6) to approximately sample from \( p(x|y, \theta) \), and by \( (y_n)_{n\in\mathbb{N}} \subset \mathbb{R}_+^\alpha \) the sequence of discrete time steps used.

Formally, starting from some \( X_0^\theta \in \mathbb{R}^d \) and \( \theta_0 \in \Theta \) we define recursively \( \{X_k^\theta : k \in \{0, \ldots, m_n\}\}, (\theta_n)_{n\in\mathbb{N}} \) on a probability space \((\Omega, \mathcal{F}, P)\): for any \( n \in \mathbb{N} \), \( X_{0:m_n}^\theta \) is a Markov chain with Markov kernel \( R_{y_n, \theta_n} \), \( X_{n-1}^\theta = X_{m_{n-1}}^\theta \) given \( F_{n-1} \), and \( \theta_{n+1} = \Pi_{\Theta} \left( \theta_n - \frac{\delta_{n+1}}{m_n} \sum_{k=1}^{m_n} \tilde{H}_{y_n}(X_k^\theta) + \nabla g(\theta_n) \right) \), where for any \( n \in \mathbb{N} \) and \( k \in \{1, \ldots, m_n\} \), \( H_{y_n}(X_k^\theta) = \nabla_\theta \log p(X_k^\theta|y, \theta_n) \) and we recall that \( \Pi_\Theta \) is the projection onto \( \Theta \), and for all \( n \in \mathbb{N} \)

\[
F_n = \sigma \left( \theta_0, \{X_{0:m_n}^\theta : \ell \in \{0, \ldots, n\}\} \right), \\
F_{n-1} = \sigma (\theta_0). 
\] (7)

Note that such a construction is always possible by Kolmogorov extension theorem (Kallemberg 2006, Theorem 5.16), hence for any \( n \in \mathbb{N} \), \( \theta_{n+1} \) is \( F_n \)-measurable. Then, as mentioned previously, we compute a sequence of approximate solutions of (1) by calculating the average of the iterates (4). The pseudocode associated with the proposed SOUL method is presented in Algorithm 1 below. Observe that, for additional efficiency, instead of generating independent Markov chains at each SA iteration, we warm-start the chains by setting \( \theta_0 = X_{m_{n-1}}^\theta \), for any \( n \in \{1, \ldots, N\} \).

### Algorithm 1 The Stochastic Optimization via Unadjusted Langevin (SOUL) method

1: Inputs: \( \theta_0, X_0^\theta \in \mathbb{R}^d, (y_n, \delta_n, m_n)_{n\in\mathbb{N}}, N \)
2: for \( n \in \{1, \ldots, N-1\} \) do
3: \( \bar{\theta}_n = X_{m_{n-1}}^\theta \)
4: \( \theta_{n+1} = \Pi_{\Theta} \left( \theta_n - \frac{\delta_{n+1}}{m_n} \sum_{k=1}^{m_n} \tilde{H}_{y_n}(X_k^\theta) + \nabla g(\theta_n) \right) \)
5: end if
6: for \( k \in \{0, \ldots, m_n - 1\} \) do
7: \( Z_{k+1}^n \sim N(0, L_k) \)
8: \( X_{k+1}^n = X_k^n + y_n \nabla \log p(X_k^n|y, \theta) + \sqrt{2\gamma_n} Z_{k+1}^n \)
9: end for
10: \( \theta_{n+1} = \Pi_{\Theta}[\theta_n + \delta_{n+1} (H_{y_n} - \nabla g(\theta_n))] \)
11: end for
12: Outputs: \( \bar{\theta}_N = \left[ \sum_{n=1}^N \delta_n \theta_n \right] / \left[ \sum_{n=1}^N \delta_n \right] \)

In Sect. 3 we prove the following results for SOUL, which we derive in more generality by analysing a broader class of methods where the Markov kernel associated with ULA is replaced by any regular and geometrically ergodic Markov kernel, see H1 and H2. For any \( a \in \mathbb{R}^d \) and \( R \geq 0 \) denote by \( B(a, R) \) the open ball centered at \( a \) and radius \( R \geq 0 \) and \( \overline{B}(a, R) \) its closure.

**Theorem 1** Assume that \( \Theta \) is convex, compact and \( \Theta \subset \overline{B}(0, R) \) with \( R \geq 0 \). In addition, assume that \( \theta \mapsto -\log(p(y|\theta)) + g(\theta) \in C^2(\Theta, \mathbb{R}) \) and is convex, that \( (x, \theta) \mapsto \log(p(x|y, \theta)) \in C^2(\mathbb{R}^d \times \Theta, \mathbb{R}) \) and that there exists \( m_1 \) such that for any \( \theta \in \Theta \) and \( x \in \mathbb{R}^d \)

\[
\sup_{x \in \mathbb{R}^d} \| \nabla \log p(x|y, \theta) \| \exp[-(m_1/4)\sqrt{1 + \|x\|^2}] < +\infty.
\]

Assume that there exist \( L_1, L_2, R_1, c \geq 0 \) and \( m_2 \) such that for any \( \theta \in \Theta \) and \( x \in \mathbb{R}^d \) we have

\[
\| \nabla_x^2 \log(p(x|y, \theta)) \| \leq L_1,
\]

\[
\| \nabla_x \nabla_y \log(p(x|y, \theta)) \| \leq L_2 \exp[(m_2/2)\sqrt{1 + \|x\|^2}]
\]

and

\[
\langle \nabla_y \log(p(x|y, \theta)) \rangle \leq -m_1 \|x\| \exp_{\overline{B}(0, R)}(x)
\]

and

\[
-m_2 \langle \nabla_x \log(p(x, \theta)) \rangle(x)^2 + c.
\]
Let \((y_n, \delta_n)_{n \in \mathbb{N}} \in ((\mathbb{R}^+)^2)^\mathbb{N}\) non-increasing, \((m_n)_{n \in \mathbb{N}} \in (\mathbb{N}^+)^\mathbb{N}\) non-decreasing and \(\sum_{n \in \mathbb{N}} \delta_n = +\infty\). Assume
\[
\sum_{n \in \mathbb{N}} \delta_n (y_n^{1/2} + (m_n y_n)^{-1}) < +\infty ,
\]
or alternatively
\[
\sum_{n \in \mathbb{N}} \delta_n (y_n^{1/2} + \delta_n / y_n^2 + (y_{n+1} - y_n) / y_n^3) < +\infty .
\]
Then almost surely, \(\hat{\theta}_\infty = \lim_{N \to +\infty} \hat{\theta}_N\) exists and \(\hat{\theta}_\infty \in \arg \min_{\theta} f\) for \(\delta_0, \gamma_0\) sufficiently small.

Note that (8) only holds if \(\lim m_n = +\infty\) (increasing batch size setting) whereas (9) holds even if \(m_n = 1\) under tighter conditions on \((\delta_n)_{n \in \mathbb{N}}\) and \((y_n)_{n \in \mathbb{N}}\) (fixed batch size setting). For constant sequences \((y_n)_{n \in \mathbb{N}}\) and \((\delta_n)_{n \in \mathbb{N}}\), Theorem 1 does not apply and \((f(\hat{\theta}_N))_{N \in \mathbb{N}}\) is biased. However, we can control the asymptotic bias using the following result.

Theorem 2 Under the same conditions on \(\Theta, (x, \theta) \mapsto \log(p(x, y|\theta))\) and \(\theta \mapsto -\log(p(y|\theta)) + g(\theta)\) as in Theorem 1, there exist \(\tilde{\delta}, \tilde{\gamma} > 0\) and \(C \geq 0\) such that if for any \(n \in \mathbb{N}\), \(\delta_n = \delta \in (0, \tilde{\delta}], \gamma_n = \gamma \in (0, \tilde{\gamma}]\) and \(m_n = 1\) then
\[
\lim \sup_{N \to +\infty} \mathbb{E}[|f(\hat{\theta}_N)| - \min f] \leq C\gamma^{1/2}.
\]

We believe Theorem 2 to be highly relevant to practitioners, as we often empirically observe that the best trade-off between accuracy and computing-time is obtained by setting \((y_n)_{n \in \mathbb{N}}\) to a constant and relatively large value (determined, e.g. from a bound on the Lipschitz constant of the target density). In our experience, this leads to a fast converging sequence that stabilises quickly close to the MLE, albeit with some bias.

The detailed theoretical analysis of the proposed SOUL method and its generalization is reported to Sect. 3. To conclude, Sect. 4 demonstrates the proposed methodology with three numerical experiments related to high-dimensional logistic regression and statistical audio analysis with sparsity promoting priors. Finally, we also study the case where \(f\) is not convex. In that case, we use the results of Kushner and Yin (2003) to establish that \((\theta_n)_{n \in \mathbb{N}}\) converges a.s. to a stationary point of the projected ordinary differential equation associated with \(\nabla f\) and \(\Theta\). We postpone this result to Section S3 in De Bortoli et al. (2019).

3 Theoretical convergence analysis for SOUL, and generalisation to other inexact MCMC kernels (SOUK)

In this section, we state our main theoretical results in a broader framework than the one introduced in Sect. 2.

After establishing notation and conventions in Sects. 3.1, 3.2 presents the general stochastic optimisation setting considered in this paper, which encompasses the MLE estimation problem (1). In order to address this class of optimisation problems, we develop a generalisation of SOUL: the Stochastic Optimisation via Unadjusted Kernel (SOUK) method. In this class of methods, ULA is replaced by a generic inexact Markov chain Monte Carlo method. We then establish our main results regarding the convergence properties of SOUK in Sect. 3.3. We conclude the section by showing that our general results apply to the specific MLE optimisation problem (1), and to the specific Langevin algorithm (6) used in SOUL in Sect. 3.4. All the proofs are postponed to the supplementary document.

3.1 Notation and convention

Denote by \(\mathcal{B}(\mathbb{R}^d)\) the Borel \(\sigma\)-field of \(\mathbb{R}^d\), and for \(f : \mathbb{R}^d \to \mathbb{R}\) measurable, \(\|f\|_\infty = \sup_{x \in \mathbb{R}^d} |f(x)|\). For a probability function on \((\mathbb{R}^d, \mathcal{B}(\mathbb{R}^d))\) and \(f\) a \(f\)-integrable function, denote by \(\mu(f)\) the integral of \(f\) with respect to \(\mu\). For \(f : \mathbb{R}^d \to \mathbb{R}\) measurable, the \(V\)-norm of \(f\) is given by \(\|f\|_V = \sup_{x \in \mathbb{R}^d} |f(x)| / V(x)\). Let \(\xi\) be a finite signed measure on \((\mathbb{R}^d, \mathcal{B}(\mathbb{R}^d))\). The \(V\)-total variation distance of \(\xi\) is defined as
\[
\|\xi\|_V = \sup_{\|f\|_V \leq 1} \left| \int_{\mathbb{R}^d} f(x) d\xi(x) \right| .
\]

If \(V = 1\), then \(\|\cdot\|_V\) is the total variation denoted by \(\|\cdot\|_{TV}\). Let \(U\) be an open set of \(\mathbb{R}^d\). We denote by \(\mathcal{C}^k(U, \mathbb{R}^p)\) the set of \(\mathbb{R}^p\)-valued \(k\)-differentiable functions, respectively the set of compactly supported \(\mathbb{R}^p\)-valued and \(k\)-differentiable functions. Let \(f : U \to \mathbb{R}\), we denote by \(\nabla f\), the gradient of \(f\) if it exists. \(f\) is said to be \(m\)-convex with \(m \geq 0\) if for all \(x, y \in \mathbb{R}^d\) and \(t \in [0, 1]\),
\[
(f(tx+(1-t)y) \leq tf(x)+(1-t)f(y)-mt(1-t)\|x-y\|^2 / 2 .
\]

For any \(a \in \mathbb{R}^d\) and \(R > 0\), denote \(B(a, R)\) the open ball centered at \(a\) with radius \(R\). Let \((X, \mathcal{X})\) and \((Y, \mathcal{Y})\) be two measurable spaces. A Markov kernel \(P\) is a mapping \(K : X \times \mathcal{Y} \to [0, 1]\) such that for any \(x \in X\), \(P(x, \cdot)\) is a probability measure and for any \(A \in \mathcal{Y}\), \(P(\cdot, A)\) is measurable. For any probability measure \(\mu\) on \((X, \mathcal{X})\) and measurable function \(f : Y \to \mathbb{R}_+\) we denote \(\mu P = \int_Y P(x, \cdot) d\mu(x)\) and \(P f = \int_Y f(y) P(\cdot, dy)\). In what follows the Dirac mass at \(x \in \mathbb{R}^d\) is denoted by \(\delta_x\) (which should not be confused with the stepsize sequence \((\delta_n)_{n \in \mathbb{N}}\)). The complement of a set \(A \subset \mathbb{R}^d\), is denoted by \(A^c\). All densities are w.r.t. the Lebesgue measure unless stated otherwise.
3.2 Stochastic Optimization with inexact MCMC methods

We consider the problem of minimizing a function \( f : \Theta \to \mathbb{R} \) with \( \Theta \subset \mathbb{R}^{d_{\Theta}} \) under the following assumption.

\[ \text{(i) } \Theta \text{ is convex, closed, } \Theta \subset B(0, M_{\Theta}) \text{ for } M_{\Theta} > 0. \]

\[ \text{(ii) There exist an open set } U \subset \mathbb{R}^{d_{\Theta}} \text{ and } f \geq 0 \text{ such that } \Theta \subset U, \text{ } f \in C^1(U, \mathbb{R}) \text{ and for any } \theta_1, \theta_2 \in \Theta \]

\[ \|\nabla f(\theta_1) - \nabla f(\theta_2)\| \leq L_f \|\theta_1 - \theta_2\|. \]

\[ \text{(iii) For any } \theta \in \Theta, \text{ there exist } H_0 : \mathbb{R}^d \to \mathbb{R}^{d_{\Theta}} \text{ and a probability distribution } \pi_0 \text{ on } (\mathbb{R}^d, B(\mathbb{R}^d)) \text{ satisfying that } \pi_0(\|H_0\|) < +\infty \text{ and } \nabla f(\theta) = \int_{\mathbb{R}^d} H_0(x) d\pi_0(x). \]

In addition, \((\theta, x) \mapsto H_0(x)\) is measurable.

Note that for the maximum marginal likelihood estimation problem (1), \( f \) corresponds to \( \theta \mapsto -\log(p(y|\theta)) + g(\theta) \), for any \( \theta \in \Theta, \text{ } H_0 : x \mapsto -\nabla_\theta \log(p(x, y|\theta)) + \nabla g(\theta) \) and \( \pi_0 \) is the probability distribution with density \( p(x|y, \theta) \).

To minimise the objective function \( f \) we suggest the use of a SA scheme which extends the one presented in Sect. 2.

More precisely, motivated by the methodology described in Sect. 2, we propose a SA scheme which relies on biased estimates of \( \nabla f(\theta) \) through a family of Markov kernels \( \{K_{r, \theta}, r \in (0, \gamma], \theta \in \Theta\} \), for \( \gamma > 0 \), such that for any \( \theta \in \Theta, \text{ } \gamma \in (0, \gamma], K_{r, \theta} \) admits an invariant probability distribution \( \pi_{r, \theta} \) on \((\mathbb{R}^d, B(\mathbb{R}^d))\). \( \gamma \) is an extra parameter which ensures the stability of the Markov kernel. In the SOUK method, the Markov kernel \( K_{r, \theta} \) stands for \( R_{r, \theta} \) for any \( r \in (0, \gamma], \theta \in \Theta \), where \( R_{r, \theta} \) is the Markov kernel associated with (6). We assume in addition that the bias associated to the use of this family of Markov kernels can be controlled with respect to \( \gamma \) uniformly in \( \theta \), i.e. for example there exists \( C > 0 \) such that for all \( \gamma \in (0, \gamma] \) and \( \theta \in \Theta, \|\pi_{r, \theta} - \pi_0\|_{TV} \leq C\gamma^\alpha \) with \( \alpha > 0 \).

Let now \((\delta_n)_{n \in \mathbb{N}} \in (\mathbb{R}^+_{\times})^\mathbb{N} \) and \((m_n)_{n \in \mathbb{N}} \in (\mathbb{N}^*)^\mathbb{N} \) be sequences of stepsizes and batch sizes which will be used to define the sequence relatively to the variable \( \theta \) similarly to (2) and (3). Let \((\gamma_n)_{n \in \mathbb{N}} \in (\mathbb{R}^+_{\times})^\mathbb{N} \) be a sequence of stepsizes which will be used to get approximate samples from \( \pi_{\delta_n} \), similarly to (6). Starting from \( X_0^n \in \mathbb{R}^d \) and \( \theta_0 \in \Theta \), we define on a probability space \((\mathcal{Q}, \mathcal{F}, \mathbb{P})\), \((X_{n-1}^n, \theta_n)_{n \in \mathbb{N}} \) by the following recursion for \( n \in \mathbb{N} \) and \( k \in \{0, \ldots, m_n - 1\} \)

\[ X_{k+1}^n = \mathcal{F}_{\theta_n} X_{k}^n \text{ given } \mathcal{F}_{n-1}, \]

\[ \theta_{n+1} = \pi_{\delta_n} \left[ \theta_n - \frac{\delta_{n+1}}{m_n} \sum_{k=1}^{m_n} H_0(X_k^n) \right], \]

where \( \mathcal{F}_{\theta_n} \) is the projection onto \( \Theta \) and \( \mathcal{F}_n \) is defined by (7). By (10), for any \( n \in \mathbb{N} \), \( \theta_{n+1} = \pi_{\delta_n} \left[ \theta_n - \frac{\delta_{n+1}}{m_n} \sum_{k=1}^{m_n} H_0(X_k^n) \right]: \pi_{\delta_n} \left[ \theta_n - \frac{\delta_{n+1}}{m_n} \sum_{k=1}^{m_n} H_0(X_k^n) \right] \]

\[ \text{where } \pi_{\delta_n} \text{ is the projection onto } \Theta \text{ and } \mathcal{F}_n \text{ is defined by (7)}. \]

The SOUK methodology allows for the use of Markov kernels beyond the one associated with the ULA algorithm considered in Sect. 2.4. Important examples include the Moreau Yosida ULA and Proximal ULA algorithms see De Bortoli et al. (2020a), De Bortoli et al. (2020b). We are currently investigating application of the SOUK framework using other samplers, in particular the Stochastic Gradient Langevin Dynamics (Welling and Teh 2011b), the underdamped Langevin algorithm (Ma et al. 2019) and the Hamiltonian Monte Carlo algorithm (Girolami and Calderhead 2011; Durmus et al. 2017; Madder et al. 2018).

Finally note that this general optimisation setting encompasses many cases of interest which are generalizations of the SOUK algorithm. If \((W, \mathcal{W}, \mu_W)\) is a probability space and \( f(\theta) = \int_W \hat{f}(\theta, w) d\mu_W(w) \) for any \( \theta \in \Theta \), with \( \hat{f} \) such that for any \( w \in W, \hat{f}(\cdot, w) \) satisfies A1 with \( \pi_0 = P_0(w, \cdot), H_0 = H_0(\cdot, w) \), where for any \( \theta \in \Theta, \text{ } P_0 : W \times X \to [0, 1] \) is a Markov kernel. Assume that \( \int_W \int_{\mathbb{R}^d} ||H_0(x, w)||_2 d\pi_0(w, dx) d\mu_W(w) < +\infty \) for any \( \theta \in \Theta \). Then, we can consider the following algorithm

\[ W_n \text{ is a sample from } \mu_W \]
X_{n,m_n}^n$ is Markov chain with kernel $K_{\gamma_n,\theta_n,W_n}$ and $X_0^n = X_{n-1,m_{n-1}}^{n-1}$ given $F_{n-1}$,
\[ \theta_{n+1} = \Pi_{\theta} \left( \theta - \frac{\delta_{i+1}}{m_i} \sum_{k=1}^{m_i} H_{\theta_0}(X_k^n, W_n) \right), \]
where $\{K_{\gamma,\theta,w} : \theta \in \Theta, \gamma (0, \gamma], w \in W\}$ is a family of Markov kernels. Similar convergence guarantees and control of the bias as the ones established in Sect. 3.3 can be obtained for this algorithm which allows to tackle the case where $f$ can be written as a sum of functions.

### 3.3 Main Results

We impose a stability condition on the stochastic process $X_{n,m_n}^n$ defined by (10) and that for any $\gamma \in (0, \gamma]$ and $\theta \in \Theta$ the iterates of $K_{\gamma,\theta}$ are close enough to $\pi_\theta$ after a sufficiently large number of iterations.

**H 1** There exists a measurable function $V : \mathbb{R}^d \to [1, +\infty)$ satisfying the following conditions.

(i) There exists $A_1 \geq 1$ such that for any $n, p \in \mathbb{N}, k \in \{0, \ldots, m_n\}$
\[ \mathbb{E}_1 = [K_{\gamma_n,\theta_n}^p V(X_n^0) | X_0^n] \leq A_1 V(X_0^n), \quad \mathbb{E}_1[V(X_0^n)] < +\infty. \]

(ii) For any $\gamma \in (0, \gamma], \theta \in \Theta$, $K_{\gamma,\theta}$ admits a stationary distribution $\pi_{\gamma,\theta}$ and there exist $A_2, A_3 \geq 1, \rho \in [0, 1)$ such that for any $\gamma \in (0, \gamma], \theta \in \Theta, x \in \mathbb{R}^d$ and $n \in \mathbb{N}$
\[ \|K_{\gamma,\theta}^n x - \pi_{\gamma,\theta} \|_V \leq A_2 \rho^n V(x), \quad \pi_{\gamma,\theta}(V) \leq A_3. \]

(iii) There exists $\Psi : \mathbb{R}^+ \to \mathbb{R}_+$ such that for any $\gamma \in (0, \gamma]$ and $\theta \in \Theta, \|\pi_{\gamma,\theta} - \pi_\theta\|_{V^{1/2}} \leq \Psi(\gamma)$.

H 1-(ii) is an ergodicity condition in $V$-norm for the Markov kernel $K_{\gamma,\theta}$ uniform in $\theta \in \Theta$. There exists an extensive literature on the conditions under which a Markov kernel is ergodic (Meyn and Tweedie 1992; Douc et al. 2018). Many MCMC algorithms enjoy geometric ergodicity such as the independence sampler (Tierney 1994), the Random Walk Metropolis–Hasting algorithm (Jarner and Hansen 2000), the Hamiltonian Monte-Carlo algorithm (Duru 2017) or the ULA algorithm (Dalalyan 2017; Durum and Moulines 2017). However, obtaining bounds which are independent from $\theta \in \Theta$ can be arduous. In Sect. 3.4, we show that such bounds can be established for ULA under regularity and curvature conditions on the family of potentials $\{U_\theta : \theta \in \Theta\}$ if for any $\theta \in \Theta$, $\pi_\theta$ admits a density proportional to $x \mapsto \exp[-U_\theta(x)]$. A popular way to establish geometric ergodicity is to derive minorization and Foster-Lyapunov drift conditions (Hairer and Mattingly (2011); De Bortoli and Durum (2019)) which can be verified on a case-by-case basis depending on the Markov kernel at hand, see Douc et al. (2018) for instance. H 1-(iii) ensures that the distance between the invariant measure $\pi_{\gamma,\theta}$ of the Markov kernel $K_{\gamma,\theta}$ and $\pi_\theta$ can be controlled uniformly in $\theta$. We show that this condition holds in the case of the Langevin Monte Carlo algorithm in Proposition S15 in De Bortoli et al. (2019). We now state our main results.

**Theorem 3** (Increasing batch size 1) Assume $A I$ and that $f$ is convex. Let $(\gamma_n)_{n \in \mathbb{N}}, (\delta_n)_{n \in \mathbb{N}}$ be sequences of non-increasing positive real numbers and $(m_n)_{n \in \mathbb{N}}$ be a sequence of positive integers satisfying $\delta_0 < 1/L_f, \gamma_0 < \gamma$ and
\[ \sum_{n=0}^{+\infty} \delta_{n+1} = +\infty, \quad \sum_{n=0}^{+\infty} \delta_{n+1}(\Psi(\gamma_n) + (m_n \gamma_n)^{-1}) < +\infty. \]

Let $(\theta_n)_{n \in \mathbb{N}}$ and $(X_{n,m_n}^n)_{n \in \mathbb{N}}$ be given by (10). Assume in addition that H 1 is satisfied and that for any $\theta \in \Theta$ and $x \in \mathbb{R}^d, \|H_0(x)\| \leq V^{1/2}(x)$. Then, the following statements hold:

(a) $(\theta_n)_{n \in \mathbb{N}}$ converges a.s. to some $\theta^* \in \arg\min_{\theta} f$;

(b) furthermore, a.s there exists $C \geq 0$ such that for any $n \in \mathbb{N}^*$
\[ f(\theta_n) - \min_{\theta} f \leq C / (\sum_{k=1}^{n} \delta_k + \epsilon). \]

**Proof** The proof is postponed to Section S1.1 in De Bortoli et al. (2019).

Note that in (10), $X_0^n = X_{n-1,m_{n-1}}^{n-1}$ for $n \in \mathbb{N}^*$. This procedure is referred to as warm-start in the sequel. An inspection of the Proof of Theorem 3 shows that $X_0^n$ could be any random variable independent from $F_{n-1}$ for any $n \in \mathbb{N}$ with $\sup_{n \in \mathbb{N}^*} \mathbb{E}[V(X_0^n)] < +\infty$. It is not an option in the fixed batch size setting of Theorem 5, where the warm-start procedure is crucial for the convergence to occur.

We extend this theorem to non-convex objective function, see Section S3 in De Bortoli et al. (2019). Under the conditions of Theorem 3 with the additional assumption that $\theta$ is a smooth manifold we obtain that $(\theta_n)_{n \in \mathbb{N}}$ converges a.s to some point $\theta^*$ such that $\nabla f(\theta^*) + n = 0$ with $n = 0$ if $\theta^* \in \mathbb{W}(\Theta)$ and $n \in \mathbb{N}(\theta^* \Theta)$ where $\mathbb{N}(\theta^*, \Theta)$ is the convex cone generated by the outer normals at point $\theta^*$, see (Aubin 2000, Chapter 2).

In the case where $K_{\gamma,\theta} = R_{\gamma,\theta}$ is the Markov kernel associated with the Langevin update (6), under appropriate conditions Proposition S15 in De Bortoli et al. (2019) shows that H 1-(iii) holds with $\Psi(y) = O(y^{1/2})$. Assume that there exist $a, b, c > 0$ such that for any $n \in \mathbb{N}^*$, $\delta_n = n^{-a}, \gamma_n = n^{-b}$ and $m_n = [n^{c}]$ then (11) is equivalent
a \leq 1, \quad a + b/2 > 1, \quad a - b + c > 1. \quad (12)

Suppose \( a \in [0, 1) \) is given. (12) reads

\[
b = 2(1-a) + \varsigma_1, \quad c = 3(1-a) + \varsigma_2, \quad \varsigma_2 > \varsigma_1 > 0.
\]

This illustrates the trade-off between the intrinsic inaccuracy of our algorithm through the family of Markov kernels (10) which do not exactly target \( \pi_0 \) and the minimization aim of our scheme. Note also that \( (\delta_n)_{n \in \mathbb{N}} \) is allowed to be constant. In this worst-case scenario, the convergence is guaranteed if \( \gamma_n = n^{-2-\varsigma_1} \) and \( m_n = \left[ n^{3+\varsigma_1} \right] \) with \( \varsigma_2 > \varsigma_1 > 0 \).

In our next result we derive an non-asymptotic upper bound of \( (\mathbb{E}[f(\hat{\theta}_n) - \min_{\Theta} f])_{n \in \mathbb{N}} \).

**Theorem 4** (Increasing batch size 2) Assume A1 and that \( f \) is convex. Let \((\gamma_n)_{n \in \mathbb{N}}, (\delta_n)_{n \in \mathbb{N}} \) be sequences of non-increasing positive real numbers and \((m_n)_{n \in \mathbb{N}} \) be a sequence of positive integers satisfying \( \delta_0 < 1/|f_x|, \gamma_0 < \gamma \). Let \((\theta_n)_{n \in \mathbb{N}} \) and \((X^n_{1:m_n})_{n \in \mathbb{N}} \) be given by (10). Assume in addition that H1 is satisfied and that for any \( \theta \in \Theta \) and \( x \in \mathbb{R}^d, \|H_0(x)\| \leq V_1^{1/2}(x) \). Then, there exists \( (E_n)_{n \in \mathbb{N}} \) such that for any \( n \in \mathbb{N}^+ \)

\[
\mathbb{E}[f(\hat{\theta}_n) - \min_{\Theta} f] \leq E_n / (\sum_{k=1}^n \delta_k),
\]

with for any \( n \in \mathbb{N}^+ \),

\[
E_n = 2M_{\phi}^2 + 2B_1M_\phi \mathbb{E}[V^{1/2}(X_0)] \sum_{k=0}^{n-1} \delta_{k+1}/(m_k \gamma_k) \\
+ 2M_\phi \sum_{k=0}^{n-1} \delta_{k+1} \Psi(\gamma_k) \\
+ 4B_1^2 \mathbb{E} \left[ V(X_0) \right] \sum_{k=0}^{n-1} \delta_{k+1}/(m_k \gamma_k)^2 \\
+ 4 \sum_{k=0}^{n-1} \delta_{k+1} \Psi(\gamma_k)^2 + B_2 \sum_{k=0}^{n-1} \delta_{k+1}^2/(m_k \gamma_k)^2, \quad (13)
\]

with \( B_1, B_2 \) given in Lemmas S3 and S4 in De Bortoli et al. (2019).

**Proof** The proof is postponed to Section S1.2 in De Bortoli et al. (2019). \( \Box \)

We recall that in the case where \( K_{\gamma, \theta} = R_{\gamma, \theta} \) is the Markov kernel associated with the Langevin update (6). Under appropriate conditions, Proposition S15 in De Bortoli et al. (2019) shows that for any \( \gamma \in (0, \gamma_0] \), \( \Psi(\gamma) = O(\gamma^{1/2}) \). In that case, if there exist \( a, b, c \geq 0 \) such that for any \( n \in \mathbb{N}^+ \), \( \delta_0 = n^{-a}, \gamma_n = n^{-b}, m_n = n^{c} \) and (12) holds, the accuracy, respectively, the complexity, of the algorithm are of orders \( (\sum_{k=1}^n \delta_k)^{-1} = O(n^{a-1}) \), respectively \( \sum_{k=0}^n m_k = O(n^{3(1-a)+\varsigma_2+1}) \) for \( \varsigma_2 > 0 \). Therefore, for a fixed target precision \( \varepsilon > 0 \), it requires that \( \varepsilon = O(n^{a-1}) \) and the complexity reads \( O(\varepsilon^{-3} (\log(1/\varepsilon)/(1-a))^{1+\varsigma_2}) \). On the other hand, if we fix the complexity budget to \( N \) the accuracy is of order \( O(N^{-(3+(1+\varsigma_2)/(1-a))^{-1}}) \). These two considerations suggest to set \( a \) close to 0. In the special case where \( a = 0 \), we obtain that the accuracy is of order \( O(n^{-1}) \), which matches the order identified in the deterministic gradient descent for convex functionals, see (Bertsekas 1997, Proposition 1.3.3) for instance in the unconstrained case. This behavior is specific to the increasing batch size setting.

Another case of interest is the fixed stepsize setting, i.e. for all \( n \in \mathbb{N} \), \( \gamma_n = \gamma > 0 \). Assume that \( (\delta_n)_{n \in \mathbb{N}} \) is non-increasing, \( \lim_{n \to +\infty} \delta_n = 0 \) and \( \lim_{n \to +\infty} m_n = +\infty \). In addition, assume that \( \sum_{n \in \mathbb{N}^+} \delta_n = +\infty \) then, by (Pólya and Szegő 1998, Problem 80, Part I), it holds that

\[
\lim_{n \to +\infty} \left[ \frac{(\sum_{k=1}^n \delta_k/m_k)}{(\sum_{k=1}^n \delta_k)} \right] = 0;
\]

\[
\lim_{n \to +\infty} \left[ \frac{(\sum_{k=1}^n \delta_k^2/\gamma_k^2)}{(\sum_{k=1}^n \delta_k^2)} \right] = 0.
\]

Therefore, we obtain that

\[
\limsup_{n \to +\infty} \mathbb{E}[f(\hat{\theta}_N) - \min_{\Theta} f] \leq 2M_\phi \Psi(\gamma).
\]

Similarly, if the stepsize is fixed and the number of Markov chain iterates is fixed, i.e. for all \( n \in \mathbb{N} \), \( \gamma_n = \gamma \) and \( m_n = m \) with \( \gamma > 0 \) and \( m \in \mathbb{N}^+ \), we obtain that

\[
\limsup_{n \to +\infty} \mathbb{E}[f(\hat{\theta}_N) - \min_{\Theta} f] \leq \mathbb{E}_1(\gamma),
\]

with \( \mathbb{E}_1(\gamma) = 2B_1 M_\phi \mathbb{E}[V^{1/2}(X_0)]/\gamma + 2M_\phi \Psi(\gamma) \). However if \( (m_n)_{n \in \mathbb{N}} \) is constant the convergence cannot be obtained using Theorem 3. Strengthening the conditions of Theorem 3 and making use of the warm-start property of the algorithm we can derive the convergence in that case.

We now are interested in the case where the batch size is fixed, i.e. \( m_n = m_0 \) for all \( n \in \mathbb{N} \). For ease of exposition we only consider \( m_0 = 1 \) and let \( \tilde{X}_{n+1} = X_n^\star \) for any \( n \in \mathbb{N} \). However, the general case can be adapted from the proof of the result stated below. More precisely we consider the setting where the recursion (10) can be written for any \( n \in \mathbb{N} \) as

\[
\tilde{X}_{n+1} \text{ has distribution } K_{\gamma_n, \delta_n}(\tilde{X}_n, \cdot) \text{ conditional to } \tilde{\mathcal{F}}_n,
\]

\[
\tilde{\theta}_{n+1} = \Pi_\Theta \left[ \tilde{\theta}_n - \delta_{n+1} H_{\theta_n}(\tilde{X}_{n+1}) \right],
\]

with \( \tilde{\theta}_0 \in \Theta, \tilde{X}_0 \in \mathbb{R}^d \) and where \( \tilde{\mathcal{F}}_n \) is given by

\[
\tilde{\mathcal{F}}_n = \sigma \left( \tilde{\theta}_0, (\tilde{X}_\ell)_{\ell \in \{0, \ldots, n\}} \right).
\]

We consider the following assumption.

\( \Box \) Springer
A2 There exists $L_H \geq 0$ such that for any $x \in \mathbb{R}^d$ and $\theta_1, \theta_2 \in \Theta$, $\|H_0(x) - H_0(x)\| \leq L_H\|\theta_1 - \theta_2\|V^{1/2}(x)$, where $V$ is given in $H_1$.

We consider a similar property as A2 on the family of Markov kernels $\{K_{\gamma, \theta} : \gamma \in (0, \tilde{\gamma}], \theta \in \Theta\}$, which weakens the assumption (Atchadé et al. 2017, H6). Indeed, we do not assume that for any $\gamma \in (0, \tilde{\gamma}]$, $\theta \mapsto K_{\gamma, \theta}$ is Lipschitz.

H2 There exist $A_1 : (\mathbb{R}_+^d)^2 \rightarrow \mathbb{R}_+$ and $A_2 : (\mathbb{R}_+^d)^2 \rightarrow \mathbb{R}_+$ such that for any $\gamma_1, \gamma_2 \in (0, \tilde{\gamma}]$ with $\gamma_2 < \gamma_1$, $\theta_1, \theta_2 \in \Theta$, $x \in \mathbb{R}^d$ and $a \in [1/4, 1/2]$

$$\|\delta K_{\gamma_1, \theta_1} - \delta K_{\gamma_2, \theta_2}\|_V \leq \left( A_1(\gamma_1, \gamma_2) + A_2(\gamma_1, \gamma_2) \right)\|\theta_1 - \theta_2\|V^{2a}(x),$$

where $V$ is given in $H_1$.

The following theorem ensures convergence properties for $(\tilde{\theta}_n)_{n \in \mathbb{N}}$ similar to the ones of Theorem 3. The proof of this result is based on a generalization of (Fort et al. 2011, Lemma 4.2) for inexact MCMC schemes.

**Theorem 5** (Fixed batch size 1) Assume A1, A2 hold and $f$ is convex. Let $\bar{\gamma} > 0$, $(\gamma_n)_{n \in \mathbb{N}}$ and $(\delta_n)_{n \in \mathbb{N}}$ be sequences of non-increasing positive real numbers satisfying $\delta_0 < 1/L_f, \gamma_0 < \bar{\gamma}$, $\sup_{n \in \mathbb{N}} |\delta_{n+1} - \delta_n|^{b_2} < +\infty$, $\sum_{n=0}^{+\infty} \delta_n = +\infty$, and

$$\sum_{n=0}^{+\infty} \delta_n \|A_1(\gamma_n, \gamma_{n+1}) + A_{2}(\gamma_n, \gamma_{n+1})\| < +\infty,$$

$$\sum_{n=0}^{+\infty} \delta_n \|\psi(\gamma_n)\| < +\infty,$$

$$\sum_{n=0}^{+\infty} \delta_n \|\gamma_n\|^{b_2} < +\infty.$$ (17)

Let $(\hat{\theta}_n)_{n \in \mathbb{N}}$ and $(\tilde{X}_n)_{n \in \mathbb{N}}$ be given by (15). Assume in addition that H1 and H2 are satisfied and that for any $\theta \in \Theta$ and $x \in \mathbb{R}^d$, $\|H_0(x)\| \leq V^{1/4}(x)$. Then, the following statements hold:

(a) $(\hat{\theta}_n)_{n \in \mathbb{N}}$ converges a.s to some $\theta^* \in \arg \min_{\theta} f$;

(b) furthermore, a.s there exists $C \geq 0$ such that for any $n \in \mathbb{N}^*$

$$f(\hat{\theta}_n) - \min_{\theta} f \leq C / \left( \sum_{k=1}^{n} \delta_k \right).$$

**Proof** The proof is postponed to Section S1.3 in De Bortoli et al. (2019).

In the case where $K_{\gamma, \theta} = R_{\gamma, \theta}$ is the Markov kernel associated with the Langevin update (6), under appropriate conditions, Propositions S15 and S16 in De Bortoli et al. (2019) show that for any $\gamma_1, \gamma_2 \in (0, \tilde{\gamma}]$ with $\tilde{\gamma} > 0$ and $\gamma_1 > \gamma_2$, $\psi(\gamma_1) = C_1 \gamma_1^{1/2}$, $A_1(\gamma_1, \gamma_2) = C_2(\gamma_1 / \gamma_2 - 1)$, $A_2(\gamma_1, \gamma_2) = C_3 \gamma_2^{1/2}$, and $C_1, C_2, C_3 \geq 0$. Thus, we obtain that the following series should converge

$$\sum_{n=0}^{+\infty} \delta_{n+1} \gamma_n^{1/2} < +\infty,$$

$$\sum_{n=0}^{+\infty} \delta_{n+1} \gamma_n^{2} < +\infty,$$

$$\sum_{n=0}^{+\infty} \delta_{n+1} \gamma_n^{3} < +\infty.$$ In addition, assume that $\delta_n = n^{-a}$ and that $\gamma_n = n^{-b}$ with $a, b > 0$. In this case, the summability conditions of Theorem 5 read

$$a \leq 1, a + b/2 > 1, 2a - 2b > 0, a + (b+1) - 3b > 1,$$

i.e. $b \in (0, 1)$, and $b \in [0, 1]$. Note that $l \neq \emptyset$ as soon as $a > 5/6$. In the special setting where $a = 1$ then the convergence in Theorem 5 occurs if $b \in (0, 1/2)$. Since $a > b+1/2$ we obtain that $\lim_{n \rightarrow +\infty} (\delta_n / \gamma_n) = 0$. This means that the stochastic gradient descent dynamic associated with $(\hat{\theta}_n)_{n \in \mathbb{N}}$ moves slower than the sequence $(\tilde{X}_n)_{n \in \mathbb{N}}$.

**Theorem 6** (Fixed batch size 2) Assume A1, A2 hold and $f$ is convex. Let $(\gamma_n)_{n \in \mathbb{N}}$, $(\delta_n)_{n \in \mathbb{N}}$, and $(\Delta_n)_{n \in \mathbb{N}}$ be sequences of non-increasing positive real numbers and $(m_n)_{n \in \mathbb{N}}$ be a sequence of positive integers satisfying $\delta_0 < 1/L_f$ and $\gamma_0 < \tilde{\gamma}$. Let $(\theta_n)_{n \in \mathbb{N}}$ and $(\tilde{X}_n)_{n \in \mathbb{N}}$ be given by (15). Assume in addition that H1 and H2 are satisfied and that for any $\theta \in \Theta$ and $x \in \mathbb{R}^d$, $\|H_0(x)\| \leq V^{1/4}(x)$. Then, there exists $(\tilde{E}_n)_{n \in \mathbb{N}}$ such that for any $n \in \mathbb{N}^*$

$$\mathbb{E}[f(\hat{\theta}_n) - \min_{\theta} f] \leq \tilde{E}_n / \left( \sum_{k=1}^{n} \delta_k \right),$$

with for any $n \in \mathbb{N}^*$,

$$\tilde{E}_n = 2M_\Theta + 2M_\Theta \sum_{k=0}^{n} \delta_k \psi(\gamma_k) + C_3 \sum_{k=0}^{n} \|\delta_{k+1} - \delta_k\| \gamma_k^{-1}$$

$$+ 2M_\Theta C_2 \sum_{k=0}^{n} \delta_{k+1} \gamma_k^{-1} \left( \gamma_{k+1}^{-1} \left( A_1(\gamma_k, \gamma_{k+1}) + A_2(\gamma_k, \gamma_{k+1}) \right) \delta_{k+1} + \delta_{k+1} \right) + C_3 \sum_{k=0}^{n} \delta_{k+1} \gamma_k^{-1}$$

$$+ C_3 (\delta_{n+1} / \gamma_n - \delta_0 / \gamma_0) + C_1 \sum_{k=0}^{n} \delta_{k+1} \gamma_k^{-1}.$$ where $C_1, C_2$ and $C_3$ are given in Lemmas S5, S8 and S7 in De Bortoli et al. (2019), respectively.

**Proof** The proof is postponed to Section S1.4 in De Bortoli et al. (2019).
Theorem 6 improves the conclusions of Theorem 4 in the case where \( y_n = y > 0 \) for any \( n \in \mathbb{N} \). Indeed, in that case, similarly to (14), assuming that \( \lim_{n \to +\infty} \delta_n = 0 \), \( \sup_{n \in \mathbb{N}} |\delta_{n+1} - \delta_n| \delta_n^{-2} < +\infty \) and that for any \( \gamma \in (0, \bar{\gamma}) \), \( A_1(\gamma, \gamma) = 0 \) and we obtain that

\[
\lim \sup_{n \to +\infty} \mathbb{E}[f(\hat{\theta}_n) - \min f] \leq \mathcal{E}_2(\gamma),
\]

with

\[
\mathcal{E}_2(\gamma) = 2M_\theta \Psi(\gamma)
\]

\[
\leq \mathcal{E}_1(\gamma) = 2B_1M_\theta \mathbb{E}[V^{1/2}(X_0^0)/\gamma] + 2M_\theta \Psi(\gamma).
\]

In the case where \( \sup_{\gamma \in (0, \bar{\gamma})} \Psi(\gamma) < +\infty \), \( \mathcal{E}_2(\gamma) \) is of order \( \mathcal{O}(\Psi(\gamma)) \) and \( \mathcal{E}_1(\gamma) \) is of order \( \mathcal{O}(\gamma^{-1}) \). Therefore if \( \lim_{\gamma \to 0} \Psi(\gamma) = 0 \), even in the fixed batch size setting, the minimum of the objective function can be approached with arbitrary precision \( \varepsilon > 0 \) by choosing \( \gamma \) small enough.

Note that the conclusions of Theorem 6 are similar to the ones of (Karimi et al. 2019, Theorem 2). In Karimi et al. (2019) the main result is a bound on \( \mathcal{E}_1(\gamma) \) and \( \mathcal{E}_1(\gamma) \) is of order \( \mathcal{O}(\gamma^{-1}) \). Therefore if \( \lim_{\gamma \to 0} \Psi(\gamma) = 0 \), even in the fixed batch size setting, the minimum of the objective function can be approached with arbitrary precision \( \varepsilon > 0 \) by choosing \( \gamma \) small enough.

To conclude, we highlight the differences between our work and Atchadé et al. (2017). Our results are based on the deterministic estimates derived in (Atchadé et al. 2017, Theorem 1, Theorem 2). However (Atchadé et al. 2017, Theorem 4, Theorem 6) rely on (i) the fact that for any \( \theta \in \Theta \), \( \pi_\theta \) is an invariant probability measure for \( K_{\gamma, \theta} \), see (Atchadé et al. 2017, H5) and (ii) a Lipschitz regularity property for \( (\gamma, \theta) \mapsto K_{\gamma, \theta} \), see (Atchadé et al. 2017, H6). Conditions (i) and (ii) do not hold if we consider unadjusted (inexact) Markov kernels. In this work we relax (Atchadé et al. 2017, H5) and (Atchadé et al. 2017, H6) by considering H1-(i), respectively H2. As an important example, the results of Atchadé et al. (2017) do not apply if the Markov kernel is the one associated with ULA, whereas in Sect. 3.4 we show that our results do hold.

### 3.4 Application to SOUL

We now apply our results to the SOUL methodology introduced in Sect. 2 where the Markov kernel \( R_{\gamma, \theta} \) with \( \gamma \in (0, \bar{\gamma}) \) and \( \theta \in \Theta \) is given by a Langevin Markov kernel and associated with recursion (6). We consider the following assumption on the family of probability distributions \( (\pi_\theta)_{\theta \in \Theta} \).

\begin{lemma}
For any \( \theta \in \Theta \), there exists \( U_\theta : \mathbb{R}^d \to \mathbb{R} \) such that \( \pi_\theta \) admits a probability density function proportional to \( x \mapsto \exp[-U_\theta(x)] \). In addition, \( (\theta, x) \mapsto U_\theta(x) \) is continuous, \( x \mapsto U_\theta(x) \) is differentiable for all \( \theta \in \Theta \) and there exists \( L \geq 0 \) such that for any \( x, y \in \mathbb{R}^d \),

\[
\sup_{\theta \in \Theta} \| \nabla_x U_\theta(x) - \nabla_x U_\theta(y) \| \leq L \| x - y \|.
\]

and \( \| \nabla_x U_\theta(0) \| : \theta \in \Theta \) is bounded.
\end{lemma}

In the case where \( K_{\gamma, \theta} = R_{\gamma, \theta} \) for any \( \gamma \in (0, \bar{\gamma}) \) and \( \theta \in \Theta \), the first line of (10) can be rewritten for any \( n \in \mathbb{N} \) and \( k \in \{0, \ldots, m_n - 1\} \)

\[
X_{k+1}^n = X_k^n - \gamma_n \nabla_x U_{\theta_n}(X_k^n) + \sqrt{2\gamma_n} Z_{k+1}^n,
\]

with \( X_0^n = X_{m_n - 1} \) if \( n \geq 1 \), \( \theta_n = \Pi_\Theta(\theta_n - \frac{\delta_n + \delta_{n+1}}{m_n} \sum_{k=1}^{m_n} H_{\theta_k}(X_k^n)) \).

Given \( (\gamma_n)_{n \in \mathbb{N}} \in (0, \bar{\gamma})^\mathbb{N}, (m_n)_{n \in \mathbb{N}} \in (\mathbb{N}^+)^\mathbb{N} \) and \( (Z_{k}^n)_{n \in \mathbb{N}, k \in \{1, \ldots, m_n\}} \), a family of i.i.d. d-dimensional zero-mean Gaussian random variables with covariance matrix identity. In the following propositions, we show that the above results hold by deriving sufficient conditions under which H1 and H2 are satisfied. Consider now the following additional tail condition on \( U_\theta \) which ensures geometric ergodicity of \( R_{\gamma, \theta} \) for any \( \theta \in \Theta \) and \( \gamma \in (0, \bar{\gamma}) \), with \( \bar{\gamma} > 0 \) which will be specified below.

### L2
There exist \( m_1, m_2 > 0 \) and \( c, R_1 \geq 0 \) such that for any \( \theta \in \Theta \) and \( x \in \mathbb{R}^d \),

\[
(\nabla_x U_\theta(x), x) \geq m_1 \| x \| \mathbb{I}_{(0, R_1)}(x) + m_2 \| \nabla_x U_\theta(x) \| ^2 - c.
\]

### L3
There exists \( L_U \geq 0 \) such that for any \( x \in \mathbb{R}^d \) and \( \theta_1, \theta_2 \in \Theta \),

\[
\| \nabla_x U_{\theta_1}(x) - \nabla_x U_{\theta_2}(x) \| \leq L_U \| \theta_1 - \theta_2 \| V(x)^{1/2}.
\]

The next theorems assert that under L1, L2 and L3, the SOUL algorithm introduced in Sect. 2 satisfies H1 and H2 and therefore Theorems 3, 4, 5 and 6 can be applied if in addition A1 and A2 hold. Under L2 define for any \( x \in \mathbb{R}^d \)

\[
V_c(x) = \exp[m_1 \mathbb{I} + \| x \| ^2/4].
\]

**Theorem 7** Assume L1 and L2. Then, H1 holds with \( V \leftarrow V_c \), \( \bar{\gamma} \leftarrow \min(1, \frac{2m_2}{m_1}) \) and \( \Psi(\gamma) = D_1 \sqrt{\gamma} \) where \( D_1 \) is given in Proposition S15 in De Bortoli et al. (2019).

**Proof** The proof is postponed to Section S1.5 in De Bortoli et al. (2019). \( \square \)
Theorem 8 Assume L1, L2, L3 and that for any \( \theta \in \Theta \) and \( x \in \mathbb{R}^d \), \( \| H_0(x) \| \leq V_e^{1/4}(x) \). H2 holds with \( V \leftarrow V_e \) and \( y \leftarrow \min(1, 2m_2) \) and for any \( \gamma_1, \gamma_2 \in (0, 1] \),
\[
A_1(\gamma_1, \gamma_2) = D_5(\gamma_1 / \gamma_2 - 1), \quad A_2(\gamma_1, \gamma_2) = D_5 \gamma_2^{1/2},
\]
where \( D_5 \) is given in Proposition S16 in De Bortoli et al. (2019).

Proof The proof is postponed to Section S1.6 in De Bortoli et al. (2019).

Finally, we discuss the dependency of the complexity of the SOUL algorithm with respect to the dimension of the latent space \( d \) in the specific case where \( \{ U_0 : \theta \in \Theta \} \) satisfies the following assumption.

L4 There exist \( m_3 > 0 \), \( R_3 \geq 0 \) such that for any \( \theta \in \Theta \) and \( x \in \mathbb{R}^d \) with \( \| x \| \geq R_3 \), \( \langle \nabla_U U_0(x), x \rangle \geq m_3 \| x \|^2 \). \( U_0 \) is convex and there exist \( C, \sigma_0 \geq 0 \) such that
\[
\sup_{\theta \in \Theta} \| \nabla_U U_0(0) \| : \theta \in \Theta \leq C(1 + d^{m_0}),
\]
where \( C \) and \( \sigma_0 \) are independent of the dimension \( d \).

In what follows, we show that under L1, L3 and L4, the constants appearing in H1 and H2 depend polynomially on the dimension of the latent space \( d \). This implies that the complexity of the SOUL algorithm is polynomial with respect to the dimension \( d \) since the constants appearing in Theorems 4 and 6 depend polynomially on the constants of H1 and H2.

Theorem 9 Assume L1, L3 and L4. Then H1 and H2 are satisfied with \( V : \mathbb{R}^d \to [1, +\infty) \) given for any \( x \in \mathbb{R}^d \) by \( V(x) = 1 + \| x \|^2 \) and \( \Psi, A_1, A_2 \) given by Theorems 7 and 8, respectively. Hence, the conclusions of Theorems 4 and 6 hold with \( (E_\alpha)_{\alpha \in \mathbb{N}} \) and \( (\tilde{E}_\alpha)_{\alpha \in \mathbb{N}} \) given for any \( \alpha \in \mathbb{N} \) by
\[
E_\alpha = A(1 + d^{m_0}) \left\{ \sum_{k=0}^{n} \delta_{k+1} \gamma_k^{1/2} + \sum_{k=0}^{n} \delta_{k+1} \sqrt{m_0 \gamma_k} \right\},
\]
and
\[
\tilde{E}_\alpha = A(1 + d^{m_0}) \left\{ \sum_{k=0}^{n} \delta_{k+1} \gamma_k^{1/2} + \sum_{k=0}^{n} \delta_{k+1} \gamma_k^{-1} \right\}
\]
\[
+ \sum_{k=0}^{n} \delta_{k+1} \gamma_k^{-3} + \sum_{k=0}^{n} \delta_{k+1} \gamma_k^{-1} + \delta_{k+1} / \gamma_k \right\},
\]
with \( \sigma_0 \in \mathbb{N} \) and \( A \geq 0 \) independent from \( d \).

Proof The proof is postponed to Section S1.7 in De Bortoli et al. (2019).

4 Numerical results

We now demonstrate the proposed methodology with three experiments that we have chosen to illustrate a variety of scenarios. Section 4.1 presents an application to empirical Bayesian logistic regression, where (1) can be analytically shown to be a convex optimisation problem with an unique solution \( \theta^* \), and where we benchmark our MLE estimate against the solution obtained by calculating the marginal likelihood \( p(y|\theta) \) over a \( \theta \)-grid by using an harmonic mean estimator. Furthermore, Sect. 4.2 presents a challenging application related to statistical audio compressive sensing analysis, where we use SOUL to estimate a regularisation parameter that controls the degree of sparsity enforced, and where a main difficulty is the high-dimensionality of the latent space \( (d = 2900) \). Finally, Sect. 4.3 presents an application to a high-dimensional empirical Bayesian logistic regression with random effects for which the optimisation problem (1) is not convex. All experiments were carried out on an Intel i9-8950HK@2.90GHz workstation running MATLAB R2018a.

4.1 Bayesian Logistic Regression

In this first experiment we illustrate the proposed methodology with an empirical Bayesian logistic regression problem (Wakefield 2013; Polson et al. 2013). We observe a set of covariates \( \{ y_i \}_{i=1}^d \in \mathbb{R}^d \), and binary responses \( \{ y_i \}_{i=1}^d \in \{0, 1\} \), which we assume to be conditionally independent realisations of a logistic regression model: for any \( i \in \{1, \ldots, d\} \), \( y_i \) given \( \beta \) and \( \xi_i \) has distribution \( \text{Ber}(s(\xi_i^T \beta)) \), where \( \beta \in \mathbb{R}^d \) is the regression coefficient, \( \text{Ber}(\alpha) \) denotes the Bernoulli distribution with parameter \( \alpha \in [0, 1] \) and \( s(u) = e^u / (1 + e^u) \) is the cumulative distribution function of the standard logistic distribution. The prior for \( \beta \) is set to be \( N(\theta_1, \sigma^2 I_d) \), \( \sigma^2 \)-dimensional Gaussian distribution with mean \( \theta_1 \) and covariance matrix \( \sigma^2 I_d \), where \( \theta \) is the parameter we seek to estimate, \( I_d = (1, \ldots, 1) \in \mathbb{R}^d \), \( \sigma^2 = 5 \) and \( I_d \) is the \( d \)-dimensional identity matrix. Following an empirical Bayesian approach, the parameter \( \theta \) is computed by maximum marginal likelihood estimation using Algorithm 1 with the marginal likelihood \( p(y|\theta) \) given by

\[
p(y|\theta) = (2 \pi \sigma^2)^{-d/2} \int_{\mathbb{R}^d} \prod_{i=1}^{d} \left[ s(v_i^T \beta)^{y_i} (1 - s(v_i^T \beta))^{1-y_i} \right] \times \exp(-\| \beta - \theta_1 \|_2^2 / (2\sigma^2)) d\beta.
\]

Lemma S18 in De Bortoli et al. (2019) shows that (19) is log-concave with respect to \( \theta \). In addition, using Lebesgue’s dominated convergence theorem A1 is satisfied for any convex and compact set \( \Theta \) with \( H_0 : \beta \mapsto -\nabla \log p(\beta, y|\theta)) \). We use the proposed SOUL methodology to estimate \( \theta^* \) for
Fig. 1 Bayesian logistic regression-Evolution of the iterates $\hat{\theta}_n$ and $\theta_n$ for the proposed method during a burn-in phase and b convergence phase. An estimate of $\theta^*$, the true maximiser of $p(y|\theta)$, is plotted as a reference.

The Wisconsin Diagnostic Breast Cancer dataset, for which $d_y = 683$ and $d = 10$, and where we suitably normalise the covariates. In order to assess the quality of our estimation results, we also calculate $p(y|\theta)$ over a grid of values for $\theta$ by using a truncated harmonic mean estimator.

To implement Algorithm 1 we derive the log-likelihood function

$$\log p(y|\beta, \theta) = \sum_{j=1}^{d_y} \left\{ y_i v_i^T \beta - \log(1 + e^{v_i^T \beta}) \right\},$$

and obtain the following expressions for the gradients used in the MCMC steps (6) and SA steps (2), respectively

$$\nabla_{\beta} \log p(\beta|y, \theta) = \sum_{i=1}^{d_y} \left\{ y_i v_i \right\} - \frac{(\beta - \theta 1_d)}{\sigma^2},$$

$$\nabla_{\theta} p(\beta|y, \theta) = (1_d, \beta - \theta 1_d) / \sigma^2.$$

Note that $\{ \beta \mapsto - \log p(\beta|y, \theta) : \theta \in \Theta \}$ satisfies L1 and L2. Therefore, since A1 holds and $\theta \mapsto - \log p(y|\theta)$ is convex we get that Theorems 7 and 8 apply and the conclusions of Theorems 1 and 2 hold. For the MCMC steps, we use a fixed stepsize $\gamma_n = 8.34 \times 10^{-5}$, and batch size $m_n = 1$, for any $n \in \mathbb{N}$. On the other hand, we consider for the SA steps, the sequence of stepsizes $\delta_n = 60n^{-0.8}$, $\theta = [ -100, 100 ]$ and $\theta_0 = 0$. Finally, we first run 100 burn-in iterations with fixed $\theta_N = \theta_0$ to warm-up the Markov chain, followed by 50 iterations of Algorithm 1 to warm-up the iterates. This procedure is then followed by $N = 10^6$ iterations of Algorithm 1 to compute $\hat{\theta}_N$.

Figure 1a shows the evolution of the iterates $\hat{\theta}_n$ during the first 100 iterations. Observe that the sequence initially oscillates, and then stabilises close to $\theta^*$ after approximately 50 iterations. Figure 1b presents the iterates $\theta_n$ for $n = 10^5, \ldots, 10^6$. For completeness, Fig. 2 shows the histograms corresponding to the marginal posteriors $p(\beta_j|y, v, \hat{\theta}_N)$, for $j = 1, \ldots, 10$, obtained as a by-product of Algorithm 1. In order to verify that the obtained estimate $\hat{\theta}_N$ is close to the true MLE $\theta^*$ we use a truncated harmonic mean estimator (THME) Robert and Wraith (2009) to calculate the marginal likelihood $p(y|\theta)$ for a range of values of $\theta$. Although obtaining the THME is usually computationally expensive, it is viable in this particular experiment as $\beta$ is low-dimensional. Given $n$ samples $(\beta_i)_{i \in [1, \ldots, n]}$ from $p(\beta|y, \theta)$, we obtain an approximation of $p(y|\theta)$ by computing

$$\hat{p}(y|\theta) = n \text{Vol}(B(\bar{\beta}, R)) \left( \sum_{k=1}^{n} \frac{p(\beta_i|y, \theta_N)}{p(\beta_i|y, \theta)} \right),$$

with $\bar{\beta} = n^{-1} \sum_{k=1}^{n} \beta_k$, and radius $R \geq 0$ such that $n^{-1} \sum_{i=1}^{n} 1_A(\beta_i) \geq 0.4$. Using $n = 6 \times 10^5$ samples, we obtain the approximation shown in Fig. 3a, where in addition to the estimated points we also display a quadratic fit (corresponding to a Gaussian fit in linear scale), which we use to obtain an estimate of $\theta^*$ (the obtained log-likelihood values are small because the dataset is large ($d_y = 683$)).

To empirically study the estimation error involved, we replicate the experiment 1000 times. Figure 3 shows the obtained histogram of $(\hat{\theta}_{ij})_{i \in [1, \ldots, n]}$, where we observe that all these estimators are very close to the true maximiser $\theta^*$. Besides, note that the distribution of the estimation error is close to a Gaussian distribution, as expected for a maximum likelihood estimator. Also, there is a small estimation bias of the order of 3%, which can be attributed to the discretisation error of SDE (5), and potentially to a small error in the estimation of $\theta^*$. We conclude this experiment by using SOUL to perform a predictive empirical Bayesian analysis on the binary responses. We split the original dataset into an 80% training set $(y^{\text{train}}, v^{\text{train}})$ of size $d_{\text{train}} = 546$, and a 20% test set $(y^{\text{test}}, v^{\text{test}})$ of size $d_{\text{test}} = 137$, and use SOUL to draw samples from the predictive distribution $p(y^{\text{test}}|y^{\text{train}}, v^{\text{train}}, \hat{\theta}_N)$. More precisely, we use SOUL to simultaneously calculate $\hat{\theta}_N$ and simulate from $p(\beta|y^{\text{train}}, v^{\text{train}}, \hat{\theta}_N)$, followed by simulation from $p(\beta|y^{\text{test}}, v^{\text{train}}, \hat{\theta}_N)$. We then estimate the maximum-a-posteriori predictive response $\hat{y}^{\text{test}}$, and measure prediction accuracy against the test dataset by computing the

4.2 Statistical audio compression

Compressive sensing techniques exploit sparsity properties in the data to estimate signals from fewer samples than required by the Nyquist–Shannon sampling theorem (Candes et al. 2006; Candès and Wakin 2008). Many real-world data admit a sparse representation on some basis or dictionary. Formally, consider an $\ell$-dimensional time-discrete signal $z \in \mathbb{R}^\ell$ that is sparse in some dictionary $\mathcal{D} \in \mathbb{R}^{\ell \times d}$, i.e., there exists a latent vector $x \in \mathbb{R}^d$ such that $z = \mathcal{D} x$ and $\|x\|_0 = \sum_{i=1}^{d} \mathbb{I}_{x_i} < \ell$. This prior assumption is be modelled using a smoothed-Laplace distribution (Lingala and Jacob 2012)

$$p(x|\theta) \propto \exp \left[ -\frac{(\theta/\lambda) \sum_{i=1}^{d} h_\lambda(x_i)}{2} \right],$$

(20)

where $h_\lambda$ is the Huber function given for any $u \in \mathbb{R}$ by

$$h_\lambda(u) = \begin{cases} u^2/2 & \text{if } |u| \leq \lambda, \\ \lambda(|u| - \lambda/2) & \text{otherwise}. \end{cases}$$

(21)

Acquiring $z$ directly would call for measuring $\ell$ univariate components. Instead, a carefully designed measurement matrix $M \in \mathbb{R}^{p \times \ell}$, with $p \ll \ell$, is used to directly observe a “compressed” signal $M z$, which only requires taking $p$ measurements. In addition, measurements are typically noisy which results in an observation $y \in \mathbb{R}^p$ modeled as $y = M z + w$ where we assume that the noise $w$ has distribution $N(0, \sigma^2 I_p)$, and therefore the likelihood function is given by

$$p(y|x) \propto \exp \left[ -\|y - A x\|_2^2/(2\sigma^2) \right],$$

where $A = M^\top \mathcal{D}$, leading to the posterior distribution

$$p(x|y) \propto \exp \left[ -\|y - A x\|_2^2/(2\sigma^2) - (\theta/\lambda) \sum_{i=1}^{d} h_\lambda(x_i) \right].$$

To recover $z$ from $y$, we then compute the maximum-a-posteriori estimate

$$\hat{\theta}_{\text{MAP}} \in \arg \min_{x \in \mathbb{R}^d} \left\{ \|y - A x\|_2^2/(2\sigma^2) + (\theta/\lambda) \sum_{i=1}^{d} h_\lambda(x_i) \right\},$$

(22)

and set $\hat{z}_{\text{MAP}} = \mathcal{D} \hat{\theta}_{\text{MAP}}$.

Following decades of active research, there are now many convex optimisation algorithms that can be used to efficiently solve (22), even when $d$ is very large (Chambolle and Pock 2016; Monga 2017). However, the selection of the value of $\theta$ in (22) remains a difficult open problem. This parameter controls the degree of sparsity of $x$ and has a strong impact on estimation performance.

A common heuristic within the compressive sensing community is to set $\theta_{\text{cs}} = 0.1 \times \|A^\top y\|_\infty/\sigma^2$, where for any $z \in \mathbb{R}^\ell$, $\|z\|_\infty = \max_{i \in \{1, \ldots, \ell\}} |z_i|$, as suggested in Kim et al.
(2007) and Figueiredo et al. (2007); however, better results can be obtained by adopting a statistical approach to estimate $\theta$.

The Bayesian framework offers several strategies for estimating $\theta$ from the observation $y$. In this experiment, we adopt an empirical Bayesian approach and use SOUL to compute the MLE $\theta^*$, which is challenging given the high-dimensionality of the latent space.

To illustrate this approach, we consider the audio experiment proposed in Balzano et al. (2010) for the “Mary had a little lamb” song. The MIDI-generated audio file $z$ has $\ell = 319$, 725 samples, but we only have access to a noisy observation vector $y$ with $p = 456$ random time points of the audio signal, corrupted by additive white Gaussian noise with $\sigma = 0.015$. The latent signal $x$ has dimension $d = 2900$ and is related to $z$ by a dictionary matrix $\Xi$ whose row vectors correspond to different piano notes lasting a quarter-second long. The parameter $\lambda$ for the prior (20) is set to $\lambda = 4 \times 10^{-5}$. We used the heuristic $\theta_{cs}$ as the initial value for $\theta$ in our algorithm. To solve the optimisation problem (22) we use the Gradient Projection for Sparse Reconstruction (GPSR) algorithm proposed in Figueiredo et al. (2007). We use this solver because it is the one used in the online MATLAB demonstration of Balzano et al. (2010), however, more modern algorithms could be used as well. We implemented Algorithm 1 using a fixed stepsize $\gamma_n = 6.9 \times 10^{-6}$, a fixed batch size $m_n = 1$, $\delta_n = 20 n^{-0.8}/d = 0.0069 n^{-0.8}$ and 100 burn-in iterations.

Note that in this problem $\theta \mapsto -\log p(y|\theta)$ is non-convex whereas $x \mapsto -\log p(x|y, \theta)$ is convex. Using Lebesgue’s dominated convergence theorem we get that A1 holds for any compact and convex set $\Theta$. Note also that $\{x \mapsto -\log p(x|y, \theta) : \theta \in \Theta\}$ satisfies L1 and L2.

The algorithm converged in approximately 500 iterations, which were computed in only 325 milliseconds. Figure 5 (left), shows the first 250 iterations of the sequence $\hat{\theta}_n$ and of the weighted average $\hat{\theta}_N$. Again, observe that the iterates oscillate for a few iterations and then quickly stabilise. Finally, to assess the quality of the estimate $\hat{\theta}_N$, Fig. 5 (right) presents the reconstruction mean squared error as a function of $\theta$. The error is measured with respect to the reconstructed signal and is given by $\text{MSE}(\hat{s}_{\text{MAP}}) = \|z^* - \Xi \hat{s}_{\text{MAP}}\|_2^2/\ell$, where $z^*$ is the true audio signal. Observe that the estimated value $\hat{\theta}_N$ is very close to the value that minimises the estimation error, and significantly outperforms the heuristic value $\theta_{cs}$ commonly used by practitioners.

Footnote 2: Each quarter-second sound can have one of 100 possible frequencies and be in 29 different positions in time.

4.3 Sparse Bayesian logistic regression with random effects

Following on from the Bayesian logistic regression in Sect. 4.1, where $p(y|\theta)$ is log-concave and hence $\theta^*$ unique, we now consider a significantly more challenging sparse Bayesian logistic regression with random effects problem. In this experiment $p(y|\theta)$ is no longer log-concave, so SOUL can potentially get trapped in local maximisers. Furthermore, the dimension of $\theta$ in this experiment is very large ($d_0 = 1001$), making the MLE problem even more challenging. This experiment was previously considered by Atchadé et al. (2017) and we replicate their setup.

Let $\{y_i\}_{i=1}^{d_y} \in \{0, 1\}$ be a vector of binary responses which can be modelled as $d_y$ conditionally independent realisations of a random effect logistic regression model,

$$y_i|x \sim \text{Ber} \left( s(v_i^T \beta + \sigma z_i^T x) \right), \quad i \in \{1, \ldots, d_y\},$$

where $v_i \in \mathbb{R}^p$ are the covariates, $\beta \in \mathbb{R}^p$ is the regression vector, $z_i \in \mathbb{R}^d$ are (known) loading vectors, $x$ are random effects and $\sigma > 0$. In addition, recall that $\text{Ber}(\alpha)$ denotes the Bernoulli distribution with parameter $\alpha \in [0, 1]$ and $s(u) = e^u/(1 + e^u)$ is the cumulative distribution function of the standard logistic distribution. The goal is to estimate the unknown parameters $\theta = (\beta, \sigma) \in \mathbb{R}^p \times (0, +\infty)$ directly from $\{y_i\}_{i=1}^{d_y}$, without knowing the value of $x$, which we assume to follow a standard Gaussian distribution, i.e. $p(x) = \exp\{ -\|x\|_2^2/2 \}/(2\pi)^d/2$. We estimate $\theta$ by MLE using Algorithm 1 to maximise (1), with marginal likelihood given by

$$p(y|\theta) = \int_{\mathbb{R}^d} \prod_{i=1}^{d_y} s(v_i^T \beta + \sigma z_i^T x)^{y_i} \times (1 - s(v_i^T \beta + \sigma z_i^T x))^{1-y_i} p(x)dx,$$
and penalty function $g(\theta) = (\lambda, \delta_0)^{-1} \sum_{j=1}^d h_{\lambda, \delta_0}(\beta_j)$, where $h_\lambda$ is the Huber function defined in (21). Using Lebesgue’s dominated convergence theorem we get that A1 holds for any compact and convex set $\Theta$.

We follow the procedure described in Atchadé et al. (2017) to generate the observations $\{y_i\}_{i=1}^d$, with $d_r = 500$, $p = 1000$ and $d = 5^3$. The vector of regressors $\beta_{true}$ is generated from the uniform distribution on $[1, 5]$ and 98% of its coefficients are randomly set to zero. The variance $\sigma_{true}$ of the random effect is set to 0.1, and the projection interval for the estimated $\sigma$ is $[10^{-5}, +\infty)$. Finally, the parameter $\lambda$ is set to $\lambda = 30$. We emphasise at this point that $\Theta$ is high-dimensional in this experiment ($d_\Theta = 1001$), making the estimation problem particularly challenging.

The conditional log-likelihood function is $\log p(x, \theta) = \sum_{i=1}^d \left\{ \sigma_i (y_i - s(v_i^T \beta + \sigma z_i^T x)) \right\} - x^T$, To implement Algorithm 1 we use the gradients

$$\nabla_x \log p(x, \theta) = \sum_{i=1}^d \left\{ \sigma_i (y_i - s(v_i^T \beta + \sigma z_i^T x)) \right\} - x^T,$$

$$\nabla_\theta \log p(x, y|\theta) = \sum_{i=1}^d \left\{ (y_i - s(v_i^T \beta + \sigma z_i^T x)) \left[ v_i z_i^T x \right] \right\}.$$

Note that $\{x \mapsto -\log p(x|y, \theta) : \theta \in \Theta\}$ satisfies L1 and L2. Therefore, since A1 holds we get that Theorems 7 and 8 apply and the conclusions of Theorem S19 in De Bortoli et al. (2019) hold. Finally, the gradient of the penalty function is given by

$$\frac{\partial}{\partial \beta_i} g(\theta) = \begin{cases} \beta_i, & |\beta_i| \leq \lambda, \\ \lambda \text{sign}(\beta_i), & |\beta_i| > \lambda, \end{cases} \frac{\partial}{\partial \sigma} g(\theta) = 0,$$

where sign denotes the sign function, i.e. for any $s \in \mathbb{R}$, $\text{sign}(s) = |s|/s$ if $s \neq 0$, and $\text{sign}(s) = 0$ otherwise.

We use $\gamma_n = 0.01$, $\delta_n = n^{-0.95}/d = 0.2 \times n^{-0.95}$, a fixed batch size $m_n = 1$, $\beta_0 = \mathbf{1}_p$ and $\sigma_0 = 1$ as initial values. Moreover, we perform $10^4$ burn-in iterations with a fixed value of $\theta_0 = (\beta_0, \sigma_0)$ to warm-up the Markov chain, and further 600 iterations of Algorithm 1 to warm-start the iterates. Following on from this, we run $N = 5 \times 10^4$ iterations of Algorithm 1 to compute $\hat{\theta}_N$. Computing this estimates required 25 seconds in total.

Figure 6 shows the evolution of the iterates throughout iterations, where we used $\|\hat{\beta}_n\|$ as a summary statistic to track the number of active components. Because the Huber penalty (21) does not enforce exact sparsity on $\beta$, to estimate the number of active components we only consider values that are larger than a threshold $\tau$ (we used $\tau = 0.005$).

From Fig. 6 we observe that $\hat{\delta}_n$ converges to a value that is very close to $\sigma_{true}$, and that the number of active components is also accurately estimated. Moreover, Fig. 7 shows that most active components were correctly identified. We also observe that $\hat{\beta}_n$ stabilises after approximately 6300 iterations, which correspond to 6300 Monte Carlo samples as $m_n = 1$. This is in close agreement with the results presented in (Atchadé et al. 2017, Figure 5), where they observe stabilization after a similar number of iterations of their highly specialised Polyga-Gamma sampler.

It is worth emphasising at this point that Atchadé et al. (2017) considers the non-smooth penalty $g(\theta) = \lambda \|\beta\|_1$ instead of the Huber loss. Consequently, instead of using the gradient of $g$, they resort to the so-called proximal operator of $g$ (Chambolle and Pock 2016). The generalisation of the SOUL methodology proposed in this paper to models that have non-differentiable terms is addressed in Vidal and Pereyra (2018), Vidal et al. (2019).
