ABSTRACT

Aims. The aim of this work is to identify the true nature of the transient EUV brightenings, called blinkers.

Methods. Co-spatial and co-temporal multi-instrument data, including imaging (EUVI/STEREO, XRT and SOT/Hinode), spectroscopic (CDS/SoHO and EIS/Hinode) and magnetogram (SOT/Hinode) data, of an isolated equatorial coronal hole were used. An automatic program for identifying transient brightenings in CDS O $\lambda 629$ Å and EUVI 171 Å was applied.

Results. We identified 28 blinker groups in the CDS O $\lambda 629$ Å raster images. All CDS O $\lambda 629$ Å blinkers showed counterparts in EUVI 171 Å and 304 Å images. We classified these blinkers into two categories, one associated with coronal counterparts and other with no coronal counterparts as seen in XRT images and EIS Fe xi 195.12 Å raster images. Around two-thirds of the blinkers show coronal counterparts and correspond to various events like EUV/X-ray jets, brightenings in coronal bright points or foot-point brightenings of large loops. These brightenings occur repetitively and have a lifetime of around 40 min at transition region temperatures. The remaining blinker groups with no coronal counterpart in XRT and EIS Fe xi 195.12 Å appear as point-like brightenings and have chromospheric/transition region origin. They take place only once and have a lifetime of around 20 minutes. In general, lifetimes of blinkers are different at different wavelengths, i.e. different temperatures, decreasing from the chromosphere to the corona.

Conclusions. This work shows that the term blinker covers a range of phenomena. Blinkers are the EUV response of various transient events originating at coronal, transition region and chromospheric heights. Hence, events associated with blinkers contribute to the formation and maintenance of the temperature gradient in the transition region and the corona.

Key words. Sun: atmosphere – Sun: corona – Methods: observational – Methods: data analysis

1. Introduction

The quasi-steady mechanism(s) that sustains the heating of the outer solar atmosphere and the solar wind is currently under intensive investigation using state-of-the-art ground- and space-based instrumentation. These observations show that small-scale salt and pepper like bipolar network magnetic fields constantly reconfigure themselves on time scales of minutes-to-hours, resulting in a complicated and dynamically evolving solar atmosphere. It is believed that magnetic reconnection and subsequent energy release is the major mechanism which can relax these constantly evolving magnetic field structures. Such small-scale energy releases seen as sudden brightenings (blinkers or extreme-ultraviolet (EUV) brightenings), fast plasma ejections (spicules or EUV/X-ray jets), etc., are omnipresent and have been reported at different heights in the solar atmosphere. It is crucial to establish links between these different events as they potentially connect the lower and upper solar atmosphere and, hence, could contribute to the transfer of mass and energy in the atmosphere (Parker 1988, Schrijver et al. 1997, 1998, Moore et al. 1998, Winebarger et al. 2002, Yamauchi et al. 2005).

EUV brightenings, also called blinkers, were first reported by Harrison (1997) in the quiet Sun, at transition region (TR) temperatures, using the Coronal Diagnostic Spectrometer (CDS; Harrison et al. 1995) on-board SoHO spacecraft. They show intensity enhancements of a factor of 2–3 (Harrison 1997, Bewsher et al. 2002) and Doppler velocities of 25–30 km s$^{-1}$ (Bewsher et al. 2003) in TR lines like O $\lambda 629.77$ Å (T $\approx 2.4 \times 10^5$ K). The average lifetime of these EUV brightenings is 16 minutes ranging from 6 to 40 min (Bewsher et al. 2002). They have also been observed in active regions (Walsh et al. 1997, Parnell et al. 2002, Bewsher et al. 2003), with slightly higher Doppler velocities of 20–40 km s$^{-1}$ (Bewsher et al. 2003). Corresponding signatures of blinkers were found in chromospheric lines (Brković et al. 2001, Brković & Peter 2003, Brooks et al. 2004, Brooks & Kurokawa 2004). Harrison et al. (1999) derived an average intensity increase of 4% and 7% in the coronal Mg x 368.9 Å and Mg x 624.9 Å lines, respectively, for these events. Bewsher et al. (2002) also detected a weak response of blinkers in these lines and concluded “that blinkers have no coronal signatures”, although “it may be simply that these lines are too weak to detect anything in”. Priest et al. (2002) suggested from simple physical models that blinkers can be produced by five different physical mechanisms, namely: the heating of cool spicular material; the containment of plasma in low-lying loops in the network; the thermal linking of cool and hot plasma at the feet of coronal loops; the heating and evaporating of chromospheric plasma in response to a coronal heating event; and the cooling and draining of hot coronal plasma when coronal heating is switched off.

Coronal jets are dynamic features which are observed as collimated ejections of plasma on small scales. They were first observed with the Solar X-ray telescope onboard the Yohkoh satellite (Shibata et al. 1992) and are believed to be the result of magnetic reconnection (Yokoyama & Shibata 1995). The X-ray Telescope (XRT; Golub et al. 2007) onboard Hinode opened a new era for studying X-ray features in tens-of-second de-
Subramanian et al.: The nature of blinkers

Fig. 1: From left: CDS O \textit{v} 629 Å raster, EUVI He \textit{ii} 304 Å image, EUVI 171 Å image and XRT Al\textsubscript{poly} image. The EUVI and XRT images have the field of view of the CDS raster over-plotted as a black rectangular box. The identified brightenings in CDS, EUVI and XRT are over-plotted with boxes in the respective images. The difference in the orientation and the coordinates of the EUVI image with respect to the CDS and XRT field-of-views is due to the difference in the viewing angles between STEREO-A and the SoHO and Hinode spacecrafts.

The paper is organized as follow: Section 2 describes the observational material. In Section 3 we outline the procedure for blinker identification in images taken in spectral lines or imager passbands covering different temperatures, i.e. chromospheric, transition region or coronal. Section 4 presents the obtained results. The discussion and conclusions are given in Section 5.

2. Data reduction and preparation

Observations obtained with the Solar Optical Telescope (SOT; Tsuneta et al. 2008), the EUV imaging spectrometer (EIS; Culhane et al. 2003, 2007) and XRT all onboard Hinode, the CDS onboard SoHO and the EUV Imager (EUVI; Howard et al. 2008) onboard STEREO were used in the analysis. Approximately 10 hours of data were taken during a dedicated observing run of an isolated equatorial coronal hole (ECH) on 2007 November 12.

X-ray images from XRT/Hinode were taken with the Al\textsubscript{poly} filter with a pixel size of 1″×1″; a field-of-view (FOV) of 370″×370″ and a cadence of 40 seconds. The data were reduced using \textit{xrt\_prep\_pro} which includes despiking, normalisation to data numbers per second to account for variations in exposure times, satellite jitter and orbital variation corrections.

EIS/Hinode was observing in a ratering mode with the 2″ slit. The data consist of a large rater with a FOV of 120″×496″ followed by 34 small rasters with a FOV of 24″×248″ taken with a cadence of 12.5 minutes, and a pixel size of 2″×1″.

Many spectral lines were available for analysis, however, in the present study only the O \textit{v} 192.9 Å (logT\textsubscript{max} = 5.4 K), Fe \textit{viii} 185.21 Å (logT\textsubscript{max} = 5.8 K), Fe \textit{x} 184.59 Å (logT\textsubscript{max} = 6.0 K) and Fe \textit{xi} 195.12 Å (logT\textsubscript{max} = 6.1 K) lines are used. The data were reduced using \textit{eis\_prep\_pro} and were corrected for EIS detector tilt and satellite orbital variation.

SOT/Hinode provided both Ca \textit{i} H images and magnetograms. The Ca \textit{i} H images were taken with a pixel size of 0.11″×0.11″ and a cadence of approximately 90 seconds. The magnetograms were taken using the Na \textit{i} 5896 Å filter with a pixel size of 0.16″×0.16″ and a cadence of 90 seconds.

Both datasets were reduced using \textit{fg\_prep\_pro}.

Full disk EUV images from EUVI/STEREO-A were taken using the 171 Å filter (dominated mostly by Fe \textit{xii}/x, but in some instances may have a large contribution from TR lines such as O \textit{v} and O \textit{vi}, more on this below) with a pixel size of 1.6″×1.6″ and a cadence of 150 seconds. The images were reduced with \textit{euvi\_prep\_pro}.

CDS/SoHO observed the He \textit{i} 584.3 Å, He \textit{ii} 303.78 Å and 303.786 Å (seen in second order; hereafter 304 Å) and O \textit{v} 629.77 Å (hereafter 629 Å) lines and a spectral window centred around 560 Å containing Ca \textit{x} and Ne \textit{vi} lines in ratering mode. Only the O \textit{v} 629 Å data were used in this paper. The data consist of a large rater with a FOV of 240″×240″ followed by 40 small rasters with a FOV of 40″×124″ taken with a cadence of 4 minutes and a pixel size of 4″×1.68″.

The data were reduced using the standard software packages for the correction of missing pixels, cosmic ray hits, CCD bias effects and flat-field effects. An intensity map of the emission from the tail, revealing the association of some jets with the expansion and eruption of coronal bright point loops (Shimojo et al. 2007; Filippov et al. 2009; Madjarska 2011). More recently, Subramanian et al. (2010) completed a statistical study of X-ray brightenings in coronal holes and quiet Sun regions. The authors found that more than 70% of the brightenings observed in coronal holes were coronal jets. However, very few jet-like events were observed in the quiet Sun. The authors also suggested that the remaining unresolved X-ray brightenings could involve two sided loop reconnection (Shibata et al. 1994) between the emerging flux and the overlying coronal field or flows in loop structures perhaps triggered by reconnection shocks from neighbouring regions. For more detailed introduction see Subramanian et al. (2010) and Madjarska (2011).

An intensity increase, i.e. a brightening, either seen in imager or spectrometer data can be a signature of various physical processes. This study aims at investigating the signature of which phenomena the EUV brightenings, often referred to as blinkers, are? We used state-of-art co-observations from imagers and spectrometers which presently observe the Sun with unprecedented spatial and temporal resolution as well as a spectral coverage of a temperature range which provides a reliable coronal diagnostic.

2. Data reduction and preparation

Observations obtained with the Solar Optical Telescope (SOT; Tsuneta et al. 2008), the EUV imaging spectrometer (EIS; Culhane et al. 2005, 2007) and XRT all onboard Hinode, the CDS onboard SoHO and the EUV Imager (EUVI; Howard et al. 2008) onboard STEREO were used in the analysis. Approximately 10 hours of data were taken during a dedicated observing run of an isolated equatorial coronal hole (ECH) on 2007 November 12.
The spectral window was obtained by integrating over the spectral line.

The CDS rasters, SOT, EUVI and XRT images were de-rotated to a common reference time in order to compensate for the solar rotation. Furthermore, the data from the different in-

Fig. 2: Blinker group 1 from top in CDS O v 629 Å, EUVI 304 Å, SOT Ca ii H, EUVI 171 Å and XRT Al poly. The corresponding magnetogram field-of-view from which the lightcurve of the positive flux was derived, is outlined by the white box on the SOT FG magnetograms and Ca ii H images.
3. Blinker identification

The first step was to identify brightenings in the CDS O \(v 629 \, \text{Å}\) rasters. For this we applied an automated brightness identification procedure described in Subramanian et al. (2010). The procedure finds intensity enhancements in the input light-curves which are above a user defined intensity threshold together with the corresponding start and end times. The input light-curves were made by summing over \(1 \times 2\) pixels, which is approximately \(4'' \times 3.4''\), and were smoothed over a time window of 3 (i.e. over 3 consecutive images) to remove unwanted spikiness in the background. As CDS was rastering completely inside the coronal hole, with no quiet Sun region, we used a single intensity threshold of 1.45\(\times\) the background. The program estimates locally the background for each lightcurve by eliminating the identified intensity peaks and averaging over the rest of the lightcurve. A duration threshold of 45 minutes was also used as blinkers can have lifetimes from 6 minutes to around 40 minutes (Bewsher et al. 2002).

The same procedure was used to identify brightenings in the EUVI 171 Å images and X-ray images with an intensity threshold of 1.35 \(\times\) and 2 \(\times\) the background, respectively, and a duration threshold of 45 minutes in order to identify the counterparts of the CDS blinkers. The input light-curves were made by summing over \(2 \times 2\) pixels, which is approximately \(3.2'' \times 3.2''\) for the EUVI 171 Å data and \(4 \times 4\) pixels, which is approximately, \(4'' \times 4''\) for the X-ray data. The intensity thresholds used in this work were calculated with a trial and error method.

Figure 1 shows sample images with the identified brightenings over-plotted. A total of 96 brightenings were identified in the CDS O \(v 629 \, \text{Å}\) raster images. These brightenings were not uniformly distributed over the field of view, instead a number of brightenings occurred close to each other, forming clusters. An event bigger than the pixel scale of one light-curve will have its imprint in adjacent light-curves. Hence, a group of identified brightenings which occurred close together and showed similar light-curves and lifetimes, were visually grouped into individual events. We identified 28 such blinker groups over the course of our observations in the CDS O \(v 629 \, \text{Å}\) data. In addition to the automatic procedure, each brightening identified in CDS O \(v 629 \, \text{Å}\) was visually cross-correlated with the EUVI 171 Å and X-ray data to search for its counterpart. We found that all CDS O \(v 629 \, \text{Å}\) blinkers have a counterpart in the EUVI 171 Å images, while only 57\% of them were present in XRT images. Thus, we classified the identified blinker groups into two categories, one with an X-ray counterpart and the other with no X-ray counterpart.

4. Results

4.1. Blinkers with X-ray counterparts

Out of the 28 identified blinker groups, 16 showed X-ray counterparts in the XRT images with a lifetime of around 40 minutes in CDS O \(v 629 \, \text{Å}\). These blinkers were further classified into two categories, those associated with pre-existing X-ray coronal bright points and those that were not. A sample of events from each case are discussed below.

The blinker group 1 (BG1) consisting of 15 automatically identified brightenings in CDS O \(v 629 \, \text{Å}\) is shown in Fig. 1. This figure also shows the blinker group as seen in EUVI 304 Å (row 2), the corresponding SOT FG magnetograms in Na i 5896 Å (row 3), SOT Ca ii H (row 4), EUVI 171 Å (row 5), and X-ray Al poly (row 6). Light-curves of BG1 (Fig. 3) in CDS O \(v 629 \, \text{Å}\) (thick black line), EUVI 171 Å (thin grey line), SOT Ca i H (thin grey line) and XRT Al poly (thick grey line) along with the light-curve of the corresponding magnetic fluxes. The light curve of the positive magnetic flux is shown with a dotted line. The asterisk symbol indicates the peak in CDS O \(v 629 \, \text{Å}\).
use them to follow the structure and dynamics of blinker groups over their lifetime. In Fig. 2, BG1 can be seen as an unresolved brightening with an elongated shape in CDS O $\lambda$ 629 Å and EUVI 304 Å with a lifetime of 45 minutes in CDS O $\lambda$ 629 Å. They show a sudden brightening with a faint ejection of plasma, i.e. a coronal jet, in EUVI 171 Å and XRT Al$_{\text{pol}}$ data with a
lifetime of 20 and 16 minutes, respectively. It is also observed as a chromospheric brightening in the SOT Ca \( \text{ii} \) images with a lifetime of 52 minutes.

![Image of light-curves](image)

**Fig. 5:** Light-curves of blinker group 2 in CDS O \( \text{v} \) 629 Å (thick black line), EUVI 171 Å (thin black line), SOT Ca \( \text{ii} \) H (thin grey line) and XRT Al\( \text{poly} \) (thick grey line) along with the light-curve of the corresponding magnetic fluxes. The light curves of the positive and the negative magnetic fluxes in absolute value are shown with dotted and dashed line, respectively. The asterisk symbol represents the peak in CDS O \( \text{v} \) 629 Å.

The corresponding magnetogram FOV is marked with a white box in Fig. 2, rows 3 & 4. In the magnetograms, we observed a cancellation of weak bipolar fluxes prior to the event and an emergence of a new positive polarity flux during the course of the event. The light-curve of this newly emerged positive polarity (Fig. 3) is very similar to the light-curves of the event in other wavelengths which suggests that the event was triggered by flux emergence. The brightening disappeared when the plasma ejection ceased as seen in the EUVI 171 Å and X-ray images. This blinker/jet falls under the category of an event with no pre-existing features at coronal temperatures, as discussed in Subramanian et al. (2010). This type of jet does not have a repetitive nature and neither do the corresponding blinkers.

Another blinker group, referred to as blinker group 2 (BG2), is discussed below. Figure 4 shows O \( \text{v} \) 629 Å data (row 1) along with EUVI 304 Å images (row 2), SOT FG magnetograms (row 3), SOT Ca \( \text{ii} \) H (row 4), EUVI 171 Å (row 5) and XRT Al\( \text{poly} \) images (row 6), taken over the course of the blinker event. The magnetic field configuration associated with this event is marked with a white box (Fig. 4, rows 3 & 4). Figure 5 shows the corresponding light-curves which have similar intensity enhancements in Ca \( \text{ii} \) H (thin grey line), CDS O \( \text{v} \) 629 Å (thick black line), EUVI 171 Å (thin black line) and XRT Al\( \text{poly} \) (thick grey line) with a lifetime of 50 minutes, 43 minutes, 12 minutes and 8 minutes in the respective wavelengths. Figure 5 also shows the light-curves of the associated positive (dotted line) and negative (dashed line) magnetic fluxes (Fig. 4, row 3).

The blinker activity started with the emergence of bipolar magnetic fluxes in the internetwork region as observed in the magnetograms. The peak intensity occurred around 04:23 UT in CDS O \( \text{v} \) 629 Å. During the course of the event the pre-existing negative polarity flux along with the emergence of weak positive polarity fluxes (Fig. 4, row 3, white box), resulted in a complete cancellation of weak positive polarities. SOT Ca \( \text{ii} \) H images (Fig. 4, row 4) clearly show point-like (within the spatial resolution of the instrument, which is close to 100 km) brightening activity at chromospheric heights which corresponds to the
strong negative polarity flux. The event is also observed at coronal heights in the EUVI 171 Å (lower corona) and in the X-ray Al poly images as seen in Fig. 4 (rows 5 & 6). The X-ray images show that loop structures were formed around the peak of the blinker activity. No plasma ejection were observed in this event at coronal heights. We can only speculate that the cancellation of the bipolar fluxes triggered the brightening of a pre-existing loop structure. The loop structure disappeared with the blinker event.

Though we see BG2 prominently in the EUVI and X-ray data, it was not identified by the identification procedure. As BG2 was followed by the formation of a coronal bright point, the corresponding light curves were dominated by this bright point (Fig. 5) at coronal temperatures (EUVI 171 Å & X-rays). This caused an estimation of a very high local background and corresponding brightening identification threshold. Consequently, the BG2 which has a weaker radiance with respect to the bright point’s radiance but a clear presence at coronal temperatures, was not identified by the automatic procedure. This example shows the limitations of our automated identification procedure which needs to be coupled with additional visual inspection in cases such as BG2.

During BG2 another positive polarity flux emerged (Fig. 4 row 3, dotted box) which moved away from the negative polarity flux discussed above (Fig. 4 row 3, solid box), resulting in the formation of a coronal bright point. Once the coronal bright point was formed at TR temperatures, it rose quickly to higher coronal temperatures (X-rays), producing a coronal jet in this region at around 05:15 UT with a corresponding blinker activity. The bright point produced two more coronal jets/blinker over the course of our observations. The bright point also showed another 6 blinker events with no coronal jets. As coronal bright points can have a range of lifetimes from 8 to 50 hours or longer, they are likely to produce several jets and blinkers over their lifetime. This blinker/jet falls under the category of events associated with a coronal bright point detected at X-ray temperatures (Subramanian et al. 2010).

4.2. Blinkers with no X-ray counterparts

The twelve remaining blinker groups, with a lifetime of around 20 minutes in CDS O v 629 Å, showed no detectable counterparts in the XRT images. One such group is discussed below, referred to as blinker group 3 (BG3).

Figure 6 shows BG3, consisting of two identified brightenings observed in CDS O v 629 Å (row 1), EUVI 304 Å (row 2) and EUVI 171 Å (row 5), while the XRT Al poly (row 6) showed no corresponding activity. The SOT FG magnetograms do not show any prominent changes of the magnetic fluxes (row 3) over the course of the event and no corresponding brightening could be detected in the Ca ii H data (row 4). This strongly suggests that the energy deposition occurred at TR heights. Figure 7 also shows the light-curves of BG3 in CDS O v 629 Å (thick black line), EUVI 171 Å (thin black line), SOT Ca ii H (thin grey line) and XRT Al poly (thick grey line). The asterisk symbol indicates the peak in CDS O v 629 Å.

4.3. Blinkers in EIS

From the above results, the question remains as to whether the observed EUVI and X-ray blinker counterparts are real coronal counterparts of blinkers or not. Both the EUVI 171 Å and the XRT Al poly filters have a wide temperature response including TR temperatures (around logT = 5.5 K). This motivated us to investigate blinkers further using spectroscopic data from Hinode/EIS which is currently the best spectrometer for studying coronal features. We could not study the brightening events discussed above with EIS, as the corresponding CDS data did not have an overlap with the EIS field-of-view. Hence, we used only the large raster from EIS which overlaps with the CDS large raster. Our study has clearly indicated so far that any blinker found in CDS O v 629.62 Å has a counterpart in EUVI 171 Å. Therefore, brightening events identified in the coronal hole in EUVI 171 Å data were used (Fig. 8) to study blinker counterparts in the EIS observations. Figure 8 shows the intensity maps of the large EIS raster along with the EUVI 171 Å and XRT image of the same region. We detected 22 brightening events in the EUVI 171 Å images that correspond to the field-of-view and timing of the large EIS raster. Out of the 22 brightening events, EIS rastered 12 of them over the course of the raster and all 12 events were clearly observed in the EIS O v 192.90 Å rasters. Similar to SDO/AIA 171 Å filter studied recently by Del Zanna et al. (2011, accepted), the EUVI 171 Å filter has strong contribution from TR emission which is coming from O v and v lines along with Fe xi which is sensitive to very cool, down to logT = 5.5 K emission. Single Gaussian line fit was applied to the EIS data to derive the intensity map, except for the O v 192.90 Å line which is blended in the blue wing by an Fe xi line. The two lines were separated by applying a double Gaussian line fit. Comparison of the CDS O v 629 Å and EIS O v 192.90 Å rasters (Fig. 9) clearly shows that we successfully subtracted the Fe xi contribution.

The coronal hole is indistinguishable in the O v 192.90 Å line (logTmax = 5.4 K), while the Fe xii 185.21 Å line (logTmax = 5.8 K) shows a trace of the coronal hole. The coronal hole is clearly visible in the Fe x 184.590 Å and Fe xi 195.12 Å coronal lines. The He ii 256 Å line is the spectral line with the
lowest formation temperature available in the EIS spectral range. However, the interpretation of this line is complicated by blends with Si x 256.37 Å, Fe xii 256.42 Å and Fe xii 256.41 Å.

4.4. Blinkers with EIS Fe xii counterparts

Out of the 12 EUVI 171 Å brightenings observed by EIS, 4 of them showed counterparts in the EIS Fe viii 185.21 Å, Fe x 184.590 Å and Fe xii 195.12 Å lines and were associated with an X-ray jet. An example event, B1, is discussed below. Figure 10 (left) shows a sequence of XRT Al poly and EUVI 171 Å images during the event. The images show a coronal bright point and a coronal jet along with the disappearance of part of the bright point. This bright point persisted throughout the 10 hours of XRT Al poly observations, producing multiple coronal jets.

Figure 10 (bottom) shows the light-curves of the blinker event B1 in XRT and EUVI 171 Å. This event falls under the category of a blinker associated with an X-ray coronal bright point jet.

The brightening B2, which is marked in Fig. 8, is another example of a blinker event with an X-ray jet. Fig. 11 (right) shows the event as seen in X-rays and EUVI 171 Å. Figure 11 (bottom) shows the light-curves of the jet peaking simultaneously in X-rays (thick line) and EUVI Fe 171 Å (thin line). This event falls under the category of blinkers with an X-ray jet, but lacking a pre-existing coronal bright point in X-rays.

Four more events showed counterparts in EIS Fe viii 185.21 Å, Fe x 184.590 Å and Fe xii 195.12 Å with no observable plasma ejection in X-rays. An example event, B3, is discussed below. Plasma ejection associated with the blinker event/X-ray jet B2 (discussed above) triggered brightenings in the nearby loop structures giving rise to B3, as seen in the EUVI 171 Å images, which then rose to higher coronal temperatures (log T = 6.0 and above). The blinker event B3 as seen in the EIS O v 192.90 Å is probably the brightening of TR loops and/or their footpoint brightening. This event belongs to the category of blinkers associated with unresolved X-ray brightenings as discussed by Subramanian et al. (2010).

4.5. Blinkers with no EIS Fe xii counterparts

The remaining 4 events showed no counterpart to the blinker in the EIS Fe x 184.590 Å and Fe xii 195.12 Å lines. Although one event was identified in X-rays, the remaining 3 events did not have a counterpart in X-rays. Two events showed corresponding point-like brightening in the EIS Fe viii 185.21 Å intensity maps (see Fig. 8), while the other two showed only a dispersed brightening in that area.

A sample brightening event B4, which is marked in Fig. 8, is discussed below. The event is clearly distinguishable in the EIS O v 192.90 Å line. In XRT data, this event falls under the category of unresolved brightening with no plasma ejection. While in the EUVI 171 Å images (Fig. 12), a point-like brightening (within the spatial resolution of the instrument, which is a few arcseconds) was observed with a corresponding formation/brightening of a loop structure, giving rise to another brightening B5 at the other end of the observed loop structure. The brightening B5 itself is a small loop structure in the EUVI 171 Å images and it was not identified in X-rays. In the EIS Fe vii 185.21 Å line, brightening B4 showed a point-like brightening (again, within the spatial resolution of the instrument, similar to EUVI), while B5 could not be identified. The B5 appearance in the EUVI 171 Å pass-band is, therefore, due to the contribution of TR emission as discussed earlier (Sec. 4.3). Figure 12 shows the light-curve of the brightening B4 in X-rays and EUVI 171 Å.
Subramanian et al.: The nature of blinkers

Fig. 8: EIS rasters of an ECH region from 2007 November 12. From left, EIS O vi 192.90 Å and Fe viii 185.21 Å intensity plots, EUVI 171 Å image over-plotted with the brightenings identified as green boxes, EIS Fe x 184.590 Å and Fe xii 195.12 Å intensity plots, XRT Al_poly image. Box symbols over-plotted on the O vi 629 Å and Fe xii 195.12 Å rasters show the 12 EUVI 171 Å brightening events, with and without coronal counterparts at Fe xii temperatures. The boxes over-plotted on the Fe viii 185.21 raster mark events with no coronal counterpart in Fe xii 195.12.

Fig. 11: The brightening B2 associated coronal jet and no pre-existing coronal feature (Fig. 8) showing plasma ejection as observed in XRT Al_poly and EUVI 171 Å images. The bottom panel shows the light-curves of the blinker event B2 peaking simultaneously in XRT (grey line) and EUVI 171 Å (black line).

Fig. 12: Brightening events B4 and B5 (Fig. 8) with no coronal counterparts in Fe xii 195.12 as observed in XRT Al_poly (top) and EUVI 171 Å (bottom) images. The bottom panel shows the light-curve of the brightening in X-rays and EUVI 171 Å.
5. Discussion and Conclusions

The aim of the present study is to identify the true nature of the transient EUV brightenings, called blinkers, or, in other words, to find what causes the observed transient brightenings. We also investigated whether they have coronal signature, i.e., the link between EUV and coronal transient features, thereby contributing to events associated with blinkers to coronal heating.

Twenty eight blinker groups were identified in CDS O v 629 Å raster images. All of them showed a counterpart in EUVI 171 Å and 304 Å images and 57% of them showed counterpart in X-rays. Although, blinkers were seen in EUVI 171 Å and X-ray images, the question on whether they can reach coronal temperatures remained open, due to the significant contribution of transition-region emission to the 171 Å pass-band and X-ray Al poly filters. A set of 12 blinker groups automatically identified in EUVI 171 Å were studied with EIS in order to determine whether these brightenings have a coronal counterpart. Out of the 12 blinker groups, 8 were found to have an EIS Fe xii 195.12 Å counterpart suggesting that events associated with the blinkers can release thermal energy directly in the solar corona. We found, in general, that blinkers are associated with various coronal events, e.g., EUV/X-ray jets, brightenings in small-scale loops (coronal bright points) or foot-point brightenings of larger loops.

Brightening events having no counterparts in X-rays and/or in EIS Fe xii 195.12 Å were also studied. They appear as point-like brightenings in CDS O v Å and EUVI 171 Å images. As they do not reach coronal temperatures (≥ log T = 6.0 K), they certainly are associated with chromospheric features, e.g., larger spicules (O'Shea et al. 2005; Madjarska et al. 2006; 2011, Sterling et al. 2010) or have transition region origin, e.g. flows in small scale TR loops (Tepica et al. 2004; Subramanian et al. 2008). Even these blinkers reach lower coronal heights (upto log T = 5.8 K). We found that some blinkers were clearly associated with newly emerging magnetic flux which caused the formation of loop structures seen in EUVI 171 Å and X-ray images. Both the loops and the blinkers faded away as the bipolar fluxes drifted away from each other similar to the quiet Sun blinker event studied by Subramanian et al. 2008, thereby confirming this to be one of the mechanisms responsible for blinkers.

Blinkers with coronal counterpart occur repetitively and have a lifetime of around 40 min at transition region temperatures, while blinkers with no coronal counterpart, i.e., with transition region/chromosphere origin, happen only once and have a duration of 20 min in average. In general, lifetimes of blinkers are different at different wavelengths, i.e., different temperatures, decreasing from the chromosphere to the corona.

The above results show that the term blinker is a ‘catch-all’ term for a vast range of transient events of coronal, transition-region or chromospheric origin. We find that the blinkers with coronal counterpart (≥ log T = 6.0 K) are associated with coronal activities and the blinkers with no counterpart above log T = 6.0 K are associated with chromospheric features. Thus, up-flows from the chromosphere and down-flows from the corona associated with these blinkers do contribute to the formation and maintenance of the temperature gradient in the transition region.
