(Dated: May 27, 2021)

In nonequilibrium systems, the relative fluctuation of a current has a universal trade-off relation with the entropy production, called the thermodynamic uncertainty relation (TUR). For systems with broken time reversal symmetry, its violation has been reported in specific models or in the linear response regime. Here, we derive a modified version of the TUR analytically in the overdamped limit for general Langevin dynamics with a magnetic Lorentz force causing time reversal broken. Remarkably, this modified version is simply given by the conventional TUR scaled by the ratio of the reduced effective temperature of the overdamped motion to the reservoir temperature, permitting a violation of the conventional TUR. Without the Lorentz force, this ratio becomes unity and the conventional TUR is restored. We verify our results both analytically and numerically in a specific solvable system.

I. INTRODUCTION

The thermodynamic uncertainty relation (TUR) states that current fluctuation has a universal trade-off relation with thermodynamic cost \[ \Phi \equiv \langle \Phi \rangle \equiv \langle \Phi \rangle^\text{ss} - \langle \Phi \rangle^\text{tot} \geq 2k_B T_{\text{ss}} \] where \( Q_\Phi \equiv \frac{\text{Var}^\text{ss}[\Phi]}{\langle \Phi \rangle^2} \langle \Delta S^\text{tot} \rangle^\text{ss} \geq 2k_B \] (1)

where \( Q_\Phi \) is the called the TUR factor for the current \( \Phi \), the variance \( \text{Var}^\text{ss}[\Phi] \equiv \langle \Phi^2 \rangle^\text{ss} - \langle \Phi \rangle^2 \) with a steady-state average \( \langle \cdot \rangle^\text{ss} \), and the Boltzmann constant \( k_B \). As an example, consider a molecular motor in a directional stochastic motion. Stochastic fluctuations and heat dissipation are two key quantities needed to be minimized for ideal performance. The above TUR enlightens that both quantities can not be minimized simultaneously and there should be a trade-off between them.

After the first discovery of the TUR for systems in the linear response regime and Markov processes on simple networks \[ \text{1, 2} \], many studies have explored its generality and applicability by investigating various systems \[ \text{3, 4} \]. Exploiting a large deviation theory or an information theory, the TUR was derived for continuous-time Markov jump processes and overdamped Langevin dynamics \[ \text{5–10} \]. It has also been reported that the TUR is related to the efficiency bound of molecular motors \[ \text{11} \], the power-efficiency trade-off relation for heat engines \[ \text{12–14} \], the generic stochastic equation for entropy production \[ \text{15–16} \], the Cramer-Rao inequality \[ \text{9, 10} \], and the symmetry of the joint distribution for the current and the entropy production \[ \text{17, 18} \] known as the detailed fluctuation theorem \[ \text{19, 21} \]. Recently, various studies have developed methods for the entropy production inference based on the TUR \[ \text{22, 23} \].

Some recent studies have shown that the TUR is violated and should be modified when dynamics has an intrinsic time scale \[ \text{26, 31} \], breaks the time-reversal symmetry \[ \text{32–34} \], or involves any odd-parity variable under time reversal such as velocity \[ \text{35–37} \]. Especially, in the underdamped Langevin dynamics, the TUR is trivially violated for reversible currents \[ \text{38} \] or for finite duration time \[ \text{38} \]. Some evidence supports that the TUR could be valid for irreversible currents in the long-time limit \[ \text{38} \], but a rigorous proof is missing. Although a variant of the TUR including dynamic activity was reported for the underdamped Langevin systems \[ \text{39} \] and then extended to systems with velocity-dependent forces \[ \text{37} \], their use is limited because their lower bounds depend on dynamic details and become trivial in the overdamped limit.

Recently, Chun et al \[ \text{34} \] showed that, in an exactly solvable underdamped Langevin system with a magnetic Lorentz force, work and heat currents violate the conventional TUR of Eq. (1) even in the small-inertia (overdamped) limit. This violation may not be surprising as the Lorentz force breaks the time reversal symmetry. Instead, they reported a modified bound for the TUR factor in the overdamped limit for infinitely long duration time. Interestingly, this modified lower bound is very similar to the conventional TUR bound except for a simple dimensionless multiplication factor. However, this system is a special harmonic system, thus the applicability of their finding to general systems should not be taken for granted.

In this paper, we consider a general underdamped dynamics with a magnetic Lorentz force and rigorously show that Chun et al’s finding is surprisingly still intact for general systems in the overdamped limit. More remarkably, this modified TUR is valid for general currents (odd under time reversal) including work and heat currents and even for a finite duration time. This modi-
The overdamped (small-mass) limit was obtained by integrating out Eq. (3) (see Appendix A and [39]) as
\[
\dot{x}(t) = G^{-1} f(x(t)) + \eta_T(t),
\]
where \(\eta_T(t)\) is a non-white Gaussian noise characterized by \(\langle \eta_T(t) \eta_T(t') \rangle = Z(t - t')\) with
\[
Z(u) = \begin{cases} 2 T G^{-1} \delta(u), & \text{for } u > 0, \\ 2 T (G^{-1})^T \delta(u), & \text{for } u < 0, \end{cases}
\]
which is clearly singular at \(u = 0\).

The symmetric part of the correlation matrix \(Z\) is
\[
Z_s(u) \equiv \frac{Z(u) + Z^T(u)}{2} = \frac{2 T B}{\gamma} \delta(u)
\]
with \(T_B = \frac{1}{1 + (B/\gamma)^2 T}\), indicating that the particle in the overdamped limit experiences a heat reservoir with the effective temperature \(T_B\) lower than the original reservoir temperature \(T\). This is consistent with the diffusion coefficient decrease for a charged Brownian particle in the presence of magnetic field, reported in [41].

The antisymmetric part of the correlation matrix plays a crucial role for featuring nonequilibrium-ness in this subtle overdamped limit, which generates a rotational probability current (curl flux), verified recently by numerical simulations for various systems [42–45]. This can be more transparent by deriving the probability current directly in the Fokker-Planck description. The systematic way to obtain a small-mass expansion of the underdamped Fokker-Planck (Kramer) equation is well established [34, 40]. Its leading order gives the overdamped Fokker-Planck (FP) equation governing
the time evolution of the position distribution function $p_\eta(x, t)$ as

$$\partial_t p_\eta(x, t) = -\nabla^T \cdot J_\eta(x, t),$$

with the probability current

$$J_\eta(x, t) = G^{-1}(f(x) - T\nabla)p_\eta(x, t),$$

where the subscript $\eta$ denotes the non-white $\eta_T$ noise. Note that the probability current has an asymmetric diffusion matrix $TG^{-1}$, which is consistent with the singular correlation matrix in Eq. 6 (explicitly shown in 39) and is also responsible for the curl flux mentioned above.

Nevertheless, the antisymmetric part of the diffusion matrix does not contribute to the time evolution of $p_\eta(x, t)$, as it is sandwiched between the same gradient operators in the FP equation. Thus, the distribution $p_\eta(x, t)$ should be identical to that for the (naive) overdamped system with the symmetric diffusion matrix $(TB/\gamma)I$, which is the symmetric part of the original diffusion matrix $TG^{-1}$.

This naive overdamped Langevin equation can be simply obtained by setting $m = 0$ in the underdamped equation of Eq. 3 as

$$\dot{x}(t) = G^{-1}f(x(t)) + \xi_{T_0}(t)$$

with a white Gaussian noise $\xi_{T_0}(t) = G^{-1}\xi_T(t)$ satisfying $\langle \xi_{T_0}(t)\xi_{T_0}(t') \rangle = Z_0(t-t') = (2TB/\gamma)\delta(t-t')$. The corresponding naive probability current is

$$J_\xi(x, t) = \left(G^{-1}f(x) - \frac{T_B}{\gamma}\nabla\right)p_\xi(x, t),$$

We will refer this naive dynamics as $\xi$-dynamics, whereas the original overdamped dynamics with the non-white noise as $\eta$-dynamics.

The equivalence of the distribution functions for both dynamics as $p_\eta(x, t) = p_\xi(x, t)$ guarantees that the average of any position-dependent observable (internal energy, system Shannon entropy, etc) does not discriminate the true overdamped $\eta$-dynamics and the naive (incorrect) $\xi$-dynamics. However, the average of path-dependent observables such as currents could depend on the antisymmetric part of the diffusion matrix. One specific example has been already reported in Ref. 39 by an explicit calculation of the average work currents for two different dynamics for an exactly solvable model, which turn out to be clearly different from each other. Therefore, one should be careful in discussing the TUR involving the current average as well as its variance in the presence of a magnetic Lorentz force.

### III. Extended FP Equation and Alternative Dynamical Observable

Consider a general accumulated current $\Phi$ in the overdamped regime as

$$\Phi(\Gamma) = \int_0^t dt' \Lambda^T(x(t')) \circ \dot{x}(t'),$$

where $\Gamma = \{x(t')| t' \in (0, t)\}$ denotes a trajectory in the state space, $\Lambda(x)$ is an arbitrary state-dependent vector (‘weight’ function), and $\circ$ represents the Stratonovich product.

It is convenient to consider the joint distribution $\hat{p}(x, \Phi, t)$ for the position and the current, from which the current average and its fluctuations can be easily calculated. As an additional stochastic variable, the current satisfies

$$\dot{\Phi}(t) = \Lambda^T(x(t)) \circ \dot{x}(t).$$

Together with Eq. 11, one can derive the extended FP equation for the naive $\xi$-dynamics as

$$\partial_t \hat{p}_\xi(x, \Phi, t) = \hat{L}_{\xi, \Phi} \hat{p}_\xi(x, \Phi, t),$$

with the FP operator

$$\hat{L}_{\xi, \Phi} = -\nabla_{\Phi}^T \cdot \left(G^{-1}f(x) - \frac{T_B}{\gamma}\nabla\phi\right)$$

where $\hat{\phi}$ denotes quantities and operators in the extended phase space and $\nabla_{\Phi} = \nabla + \partial_\Phi \Lambda(x)$ is a tilted gradient operator. For detailed derivation, see Appendix B. By integrating out over $\Phi$ in Eq. 13, one can recover the ordinary FP equation with the probability current given in Eq. 12.

Now, let us derive the extended FP equation for the original $\eta$-dynamics. As the $\eta_T$ noise is non-white, it is not straightforward to derive the extended FP operator directly. Thus, we again go back to the underdamped version and take the small-mass expansion. After a lengthy but straightforward calculation (shown in Appendix C), we obtain

$$\partial_t \hat{p}_\eta(x, \Phi, t) = \hat{L}_{\eta, \Phi} \hat{p}_\eta(x, \Phi, t),$$

with

$$\hat{L}_{\eta, \Phi} = -\nabla_{\Phi}^T G^{-1} \left(f(x) - T\nabla\phi\right) = \hat{L}_{\xi, \Phi} - \partial_\Phi \varphi(x),$$

where the scalar function

$$\varphi(x) = -T\nabla^T G^{-1} \Lambda(x)$$

with $G^{-1} = (G^{-1} - (G^{-1})^T)/2$. Note that the gradient operator in Eq. 19 works only inside the scalar function (not on the distribution function). This scalar function is originated from the antisymmetric part of the diffusion matrix and contributes to the time evolution of the joint distribution, in contrast to the ordinary distribution case. Thus, $\hat{p}_\eta(x, \Phi, t) \neq \hat{p}_\xi(x, \Phi, t)$ and thus $\langle A(\Phi) \rangle_\eta \neq \langle A(\Phi) \rangle_\xi$ for an arbitrary function $\Lambda(\Phi)$.

Our key observation is that the extended FP operator $\hat{L}_{\eta, \Phi}$ has the same mathematical structure with the time evolution operator $\hat{L}_{\xi, \Phi}$ for the joint distribution $\hat{p}_\xi(x, \Phi, t)$ with the alternative dynamic observable

$$\Psi(\Gamma) = \Phi(\Gamma) + \int_0^t dt' \varphi(x(t'))$$

where
in the $\xi$-dynamics. In short, we find the operator correspondence relation

$$\hat{L}_{\eta, \Phi} = \hat{L}_{\xi, \Psi} \bigg|_{\Phi \rightarrow \Phi} ,$$  \hspace{1cm} (21)

which is easily verified from Eq. (13) in Appendix B for the explicit derivation of $\hat{L}_{\xi, \Psi}$ and Eq. (18). Note that the alternative dynamic observable $\Psi$ and the original current $\Phi$ differ by the accumulated state-dependent observable $\varphi$, meaning that $\Psi$ is not antisymmetric under time reversal in contrast to $\Phi$.

The correspondence relation between the extended FP operators implies that the random variables $\Phi$ in the $\eta$-dynamics and $\Psi$ in the $\xi$-dynamics should be equivalent in their distributions at any time during the evolution, starting with the same initial distribution. In other words, we can identify the equivalence relations as

$$\dot{p}_\eta(x, \Phi, t) = \dot{p}_\xi(x, \Psi, t) \bigg|_{\Phi \rightarrow \Phi} \quad \text{and} \quad \langle A(\Phi) \rangle_\eta = \langle A(\Psi) \rangle_\xi ,$$  \hspace{1cm} (22)

Using these relations, we can avoid complex calculations for the averages, caused by the singular nature of the non-white noise in the original $\eta$-dynamics. Figure 2 shows the schematic description of this relation. For example, the current average and its variance in the $\eta$-dynamics are identical to those of the alternative dynamic observable in the $\xi$-dynamics as

$$\langle \Phi \rangle_\eta = \langle \Psi \rangle_\xi \quad \text{and} \quad \text{Var}_\eta[\Phi] = \text{Var}_\xi[\Psi] ,$$  \hspace{1cm} (23)

which are useful to calculate the TUR factor $Q_\Phi$ for the original $\eta$-dynamics.

The time evolution of the alternative dynamic observable $\Psi$ reads from Eq. (20)

$$\dot{\Psi}(t) = \Lambda^{\eta}(x(t)) \circ \dot{x}(t) + \varphi(x(t)) ,$$  \hspace{1cm} (24)

yielding the relation between the average current rates

$$\langle \dot{\Phi} \rangle_\eta = \langle \dot{\Psi} \rangle_\xi = \langle \dot{\Phi} \rangle_\xi + \langle \varphi \rangle_\xi .$$  \hspace{1cm} (25)

It is worth mentioning that the non-zero average scalar term $\langle \varphi \rangle_\xi$ represents the difference of two different averages of the current $\Phi$.

As in the traditional stochastic thermodynamics like in the $\xi$-dynamics, the average current rate in the $\eta$-dynamics is also written in an integral form involving the probability current (shown in Appendix D) as

$$\langle \dot{\Phi} \rangle_\eta = \int dx \, \Lambda^{\eta}(x) \cdot J_\eta(x, t) .$$  \hspace{1cm} (26)

The average rate of $\Psi$ in the $\xi$-dynamics is also written in a similar form, using Eq. (24), as

$$\langle \dot{\Psi} \rangle_\xi = \int dx \, (\Lambda^{\xi}(x) \cdot J_\xi(x, t) + \varphi(x)p_\xi(x, t))$$  \hspace{1cm} (27)

$$\equiv \int dx \, \Lambda^{\xi}(x) \cdot J_\xi(x, t)$$  \hspace{1cm} (28)

with the effective probability current

$$J_\xi(x, t) = J_\xi(x, t) - TG_{\alpha}^{-1} \nabla p_\xi(x, t)$$  \hspace{1cm} (29)

$$= G^{-1}(f - T \nabla) p_\xi(x, t) ,$$  \hspace{1cm} (30)

where we used Eq. (19) and the relation $\int dx \, (G_{\alpha}^{-1} \nabla)^T \Lambda(x) p_\xi(x, t) = 0$. Comparing this with $J_\eta(x, t)$ in Eq. (10), we find the relation of

$$J_\xi(x, t) = J_\eta(x, t) ,$$  \hspace{1cm} (31)

with the distribution equivalence of $p_\eta(x, t) = p_\xi(x, t)$. This relation along with Eqs. (24) and (28) confirms Eq. (25).

To discuss the TUR, we consider the steady-state entropy production rate for the $\eta$-dynamics. Its stochastic version in the steady state can be written as

$$\dot{S}^{\text{tot}}(t) = \Lambda_S^{\eta}(x(t)) \circ \dot{x}(t) + \Lambda_S(x) = \frac{GJ_{\eta}^{\text{ss}}(x)}{T p_{\eta}^{\text{ss}}(x)} $$  \hspace{1cm} (32)

where the superscript ‘ss’ denotes a steady-state quantity such as $J_{\eta}^{\text{ss}}(x) = G^{-1}(f - T \nabla) p_{\eta}^{\text{ss}}(x)$ with the steady-state distribution $p_{\eta}^{\text{ss}}(x)$ (see Appendix D for its derivation). Using Eqs. (32) and (20), we obtain the average steady-state rate

$$\langle \dot{S}^{\text{tot}} \rangle_\eta = \frac{\gamma}{T} \int dx \frac{|J_{\eta}^{\text{ss}}(x)|^2}{p_{\eta}^{\text{ss}}(x)}$$  \hspace{1cm} (33)

$$= \frac{\gamma}{T} \int dx \frac{|J_{\xi}^{\text{ss}}(x)|^2}{p_{\xi}^{\text{ss}}(x)} \equiv \langle \dot{\Sigma} \rangle_\xi^{\text{ss}} $$  \hspace{1cm} (34)

where the relation of Eq. (31) is used with $J_{\xi}^{\text{ss}}(x) = G^{-1}(f - T \nabla) p_{\xi}^{\text{ss}}(x)$ and Eq. (25) guarantees $\langle \dot{S}^{\text{tot}} \rangle_\eta = \langle \dot{\Sigma} \rangle_\xi^{\text{ss}}$ with the corresponding alternative dynamic variable $\Sigma$, defined as $\dot{\Sigma}(t) = \dot{S}^{\text{tot}}(t) + \varphi_S(x(t))$ with the scalar function $\varphi_S(x) = -T \nabla \cdot G_{\alpha}^{-1} \Lambda_S(x)$ (see the explicit calculation in Appendix D).

Using Eqs. (23) and (24), the TUR factor $Q_\Phi$ for the $\eta$-dynamics is now expressed in terms of quantities in the $\xi$-dynamics as

$$Q_\Phi = \frac{\text{Var}_\eta[\Phi]}{(\langle \dot{\Phi} \rangle_\eta)^2} \langle \Delta S^{\text{tot}} \rangle_\eta = \frac{\text{Var}_\xi[\Psi]}{(\langle \dot{\Psi} \rangle_\xi)^2} \langle \Delta \Sigma \rangle_\xi^{\text{ss}} \equiv R_\psi$$  \hspace{1cm} (35)
with $\langle \Delta \Sigma \rangle^k_\xi = \int_0^t dt' \langle \dot{\Sigma}(t') \rangle^k_\xi$. We refer to $R_\Psi$ as the alternative TUR factor for $\Psi$ in the perspective of the $\xi$-dynamics. In the normal overdamped $\xi$-dynamics, the conventional TUR should be valid for general irreversible currents of the generic type in Eq. (13) with an arbitrary duration time $t$. However, our alternative dynamic observable $\Psi$ is not of the generic type, but is given by the combination of the current $\Psi$ and the accumulated state-dependent variable $\varphi$. Furthermore, $\Delta \Sigma$ is not the entropy production for the $\xi$-dynamics (see Eq. (11) for the true entropy production). Thus, the alternative TUR factor $R_\Psi$ may violate the conventional TUR bound of $2k_B$. In the next section, we show that this violation indeed occurs and derive a new bound analytically.

IV. MODIFIED TUR

The derivation of the conventional TUR is based on the observation that the TUR is a special case of the Cramer-Rao (CR) inequality [47, 48]. Here, we take a smaller but slightly different approach from the conventional one adopted in Refs. [3, 10], to derive a new lower bound for the alternative TUR factor $R_\Psi$ in the $\xi$-dynamics.

The CR inequality generally provides a lower bound of the variance of any dynamic observable $O(\Gamma)$ in a stochastic process with a parameter $\theta$ as

$$\text{Var}_\theta [O] \left/ \partial_{\theta} \langle O \rangle_\theta \right|_\xi \geq I(\theta) \geq 1,$$

where $\langle O \rangle_\theta = \int d\Omega O(\Gamma) P_\theta(\Gamma)$ with the trajectory probability $P_\theta(\Gamma)$ and the Fisher information is defined as

$$I(\theta) = \langle -\partial_{\theta}^2 \ln P_\theta(\Gamma) \rangle_\theta.$$

If the dynamics of our interest is defined at $\theta = 0$, it is crucial to find an appropriate modified dynamics with a nonzero $\theta$, which yields $\lim_{\theta \to 0} \partial_{\theta} \langle O \rangle_\theta = \langle O \rangle_0$. Then, the (alternative) TUR factor in Eq. (35) naturally comes into the CR inequality at $\theta = 0$.

We take the $\xi$-dynamics as the unperturbed one at $\theta = 0$. Similar to the perturbation term in the previous studies [3, 10], we consider a linear perturbation on the force as

$$f_\theta(x) = f(x) + \theta G J_{\xi}^{ss}(x).$$

The steady-state distribution $P_{\xi}^{ss}(x)$ satisfies $\nabla^T \cdot J_{\xi}^{ss}(x) = 0$ and we also find $\nabla^T \cdot J_{\xi}^{ss}(x) = 0$ as well from Eq. (29). In the previous studies for the conventional TUR [3, 10], $\gamma J_{\xi}^{ss}(x)$ was used instead of $G J_{\xi}^{ss}(x)$ in the perturbation term of Eq. (35).

It is easy to see that the perturbed steady-state distribution is identical to the unperturbed one, i.e. $P_{\xi,\theta}^{ss}(x) = P_{\xi}^{ss}(x)$, as the perturbed steady-state probability current

$$J_{\xi,\theta}^{ss}(x) = \left( G^{-1} f_\theta(x) - \frac{T_B}{\gamma} \nabla \right) P_{\xi,\theta}^{ss}(x).$$

satisfies the steady-state condition of $\nabla^T \cdot J_{\xi,\theta}^{ss}(x) = 0$. The perturbed effective probability current in the steady state becomes

$$J_{\xi,\theta}^{ss}(x) = G^{-1} f_\theta(x) - T B \nabla p_{\xi,\theta}^{ss}(x) = (1 + \theta) J_{\xi}^{ss}(x),$$

which yields $\langle \dot{\Psi} \rangle_{\xi,\theta}^{ss} = (1 + \theta) \langle \dot{\Psi} \rangle_{\xi}^{ss}$ from Eq. (22), thus we find

$$\partial_{\theta} \langle \dot{\Psi} \rangle_{\xi,\theta}^{ss} = \langle \dot{\Psi} \rangle_{\xi}^{ss}.$$ (41)

The remaining task is to express the Fisher information $I(\theta)$ at $\theta = 0$ in terms of $\langle \Delta \Sigma \rangle_{\xi}^{ss}$. Using the Onsager-Machlup theory [40] in Eq. (11), the trajectory probability is written as

$$P_\theta[\Gamma] = \frac{p_{\xi,\theta}^{ss}(x(0)) N_\theta e^{-\frac{\gamma}{T_B} \int_0^t dt' [\dot{x}(t') - G^{-1} f_\theta(x(t'))]^2}}{2 \pi k_B T_B},$$

where the initial probability $p_{\xi,\theta}^{ss}(x(0))$ and the normalization factor $N_\theta$ are $\theta$-independent. Then, one can easily find the explicit form of the Fisher information from Eq. (37) as

$$I(\theta) = \frac{t \gamma}{2 \pi B} \int dx \left| J_{\xi}^{ss}(x) \right|^2,$$

which is $\theta$-independent. Using Eq. (34), we find

$$I(\theta) = \frac{T_B}{2 \pi B} (\dot{\Sigma})_{\xi}^{ss} = \frac{T_B}{2 \pi B} \langle \Delta \Sigma \rangle_{\xi}^{ss}.$$ (44)

Using Eqs. (35), (36) and (11) along with Eq. (8) and setting $\theta = 0$, we finally obtain the modified TUR for the overdamped $\eta$-dynamics as

$$Q_\Psi = \frac{\text{Var}_\eta \left[ \Phi \right]}{\langle \Phi \rangle_\eta^2} \langle \Delta S_{\text{tot}}^{\eta} \rangle_{\xi}^{ss} = R_\Psi \geq 2k_B \frac{T_B}{B} \frac{2k_B}{1 + (B/\gamma)^2},$$ (45)

which is the main result of our paper. Note that we restored the Boltzmann constant $k_B$ here. The result shows that the Lorentz magnetic force always lowers the threshold of the TUR factor, which weakens the trade-off constraint. Obviously, the conventional TUR is recovered at $B = 0$. Interestingly, Chun et al. [34] found the same form of the TUR lower bound in an exactly solvable linear model for the work and heat current in the long-time ($t \to \infty$) limit. Our result applies to a general current in a general nonlinear system for an arbitrary duration time. In the next section, we derive the TUR factors exactly for the linear model for a finite duration time and confirm the validity of our modified TUR.

The equality condition of the modified TUR can be determined by the equality condition of the Cramer-Rao inequality in Eq. (36) as

$$\partial_{\theta} \ln P_\theta(\Gamma) \propto O(\Gamma) - \langle O \rangle_\theta$$ for any $\Gamma$. (46)
After a straightforward calculation following a similar procedure in Ref. [3], we find that the equality holds with the two constraints as

$$\Lambda(x) = \frac{J^{ss}_\eta(x)}{p^{ss}_\eta(x)} \tag{47}$$

with an arbitrary constant, $\mu$, and

$$\langle \hat{S}^{tot}_{\eta} \rangle^{ss} = \gamma \frac{J^{ss}_\eta(x)}{p^{ss}_\eta(x)}^2 - \gamma \frac{\nabla^{\top} G^{-1}_\eta J^{ss}_\eta(x)}{p^{ss}_\eta(x)} \tag{48}.$$

Note that the entropy production current automatically satisfies the first constraint for $B = 0$, but not for $B \neq 0$ (see Eq. (52)). Other currents may satisfy the first constraint for some specific dynamics (see the example in the next section), but not in general. The second constraint is independent of the choice of currents, $\Lambda(x)$, and the normal overdamped motion is expected with the parallel plane is smaller as $T > T_B$.

In the next section, we will show this example explicitly, where the equality of the modified TUR holds out of equilibrium.

It is straightforward to extend our modified TUR to the $\eta$-dynamics with an arbitrary initial state. This generalization in the normal overdamped $\xi$-dynamics was reported recently in [50, 51]. We also study this generalization in the $\eta$-dynamics and find the modified TUR with an arbitrary initial state for a finite duration time $t$ as

$$\text{Var}_\eta \left[ \frac{\partial}{\partial t} H(t) \right] \langle \Delta S^{tot}_{\eta} \rangle \geq 2k_B \frac{T_B}{T} T \tag{49},$$

where $H(t)$ is the current at the final time $t$ of duration and Eq. (49) is recovered in the steady state. The derivation details are given in Appendix C.

A generalization to higher dimensional cases is also possible. The overdamped motion in the perpendicular plane to the magnetic field follows the same behavior discussed before with the effective temperature $T_B$. In the parallel plane, the particle does not feel the Lorentz force and the normal overdamped motion is expected with the temperature $T$. The contribution to the Fisher information in Eq. (13) from this normal overdamped motion in the parallel plane is smaller as $T > T_B$, thus the total Fisher information is smaller than the entropy production of the $\eta$-dynamics in Eq. (40). Therefore, our main result still holds in higher dimensions, even though the TUR equality condition can not be satisfied for non-zero $B$. For details, see Appendix B.

V. EXAMPLE

To confirm our main result, we consider an analytically solvable system with a linear force as

$$f(x) = -Fx \quad \text{with} \quad F = \begin{pmatrix} k & -\epsilon \\ \epsilon & k \end{pmatrix}. \tag{50}$$

The diagonal elements represent a force applied by a harmonic potential with spring constant $k$, while the off-diagonal elements indicate a nonequilibrium driving force with strength $\epsilon$. This system has been investigated in various studies [24, 37, 38, 52, 54], because it is analytically solvable. In the remaining text, we will omit the subscript $\eta$ for brevity.

We consider two accumulated currents of work $W$ done on the system and heat $Q$ dissipated into the reservoir, which are defined in Eq. (13) with weight functions

$$A_W(x) = W x \quad \text{with} \quad W = \begin{pmatrix} 0 & \epsilon \\ -\epsilon & 0 \end{pmatrix} \quad \text{for work } W, \tag{51}$$

$$A_Q(x) = Q x \quad \text{with} \quad Q = -F \quad \text{for heat } Q. \tag{52}$$

Since the model basically belongs to the Ornstein-Uhlenbeck process [40, 53, 56], the steady-state distribution $p^{ss}(x)$ should be Gaussian as

$$p^{ss}(x) = \frac{1}{\sqrt{\det(2\pi C)}} \exp \left\{ -\frac{1}{2} x^T C^{-1} x \right\} \tag{53}$$

with the covariance matrix $C = \langle xx^T \rangle$. From the steady-state condition, we can easily find in Eq. (33) as

$$C = \frac{\gamma T}{\gamma k + \epsilon B} I, \quad \tag{54}$$

which is stable for $\gamma k + \epsilon B > 0$. The steady-state probability current is then obtained from Eq. (11) as

$$J^{ss}(x) = \frac{1}{\gamma} W x p^{ss}(x). \tag{55}$$

The steady-state averages of work $W$ and heat $Q$ are calculated by Eq. (26) as

$$\langle W \rangle^{ss} = t \int dx \Lambda_W(x) \cdot J^{ss}(x) \tag{56}$$

$$= t \frac{2\epsilon^2 T}{\gamma k + \epsilon B} = \langle Q \rangle^{ss}, \tag{57}$$

which agrees with the result in [39]. The scalar function in Eq. (19) becomes a constant as $\phi(x) = 2\epsilon BT/(\gamma^2 + B^2)$ for both currents, which represents the difference between the true and the naive average in Eq. (25).
FIG. 3. Duration-time-dependent behavior of the TUR factors (a) for work $Q_W$, (b) for heat $Q_Q$, and (c) for the entropy production $Q_S$. The symbols represent the numerical data from the underdamped dynamics with $m_0 = 0.001$. Lines represent the analytic results obtained in the overdamped $\eta$-dynamics. Black dotted lines indicate the modified TUR bound in Eq. (15). We fixed (a) $B_0 = 0.5$ with several values of $\epsilon_0 = 0.1$ (red circle), $0.5$ (blue triangle), and $1.0$. (cyan square) for work; (b) $B_0 = 0.75$ with $\epsilon_0 = -0.6$ (red circle), $-0.5$ (blue triangle), $0.6$ (cyan square), and $2.0$ (violet diamond) for heat, and (c) $B_0 = 0.6$ and $\epsilon_0 = -0.1$ (red circle), $1.0$ (blue triangle), $1.875$ (cyan square), and $2.0$ (violet diamond) for entropy production.

One can also consider the total entropy production $\Delta S^{\text{tot}}$ with $A_S(x) = GJ^m(x)/[T P^m(x)]$ in the steady state (see Eq. (82)). Using Eq. (55), we find the weight function as

$$A_S(x) = S x = G W / (T \gamma)$$

from which we obtain $\langle \Delta S^{\text{tot}} \rangle = \langle Q \rangle / T$ and the corresponding scalar function $\varphi_S(x) = 2\epsilon B / (\gamma^2 + B^2)$, as expected.

The most complex task is to find the variance of work, heat, and entropy production. From the extended FP equation of $\rho(x, \Phi, t)$ in Eqs. (17) and (18), we derive the formal solution for the variance in terms of auxiliary matrices (see Appendix C). Finding the explicit forms of the auxiliary matrices, we obtain the variance and the TUR factor in the steady state with a finite duration time $t_0$.

First, the TUR factor for work is given as

$$Q_W = \frac{2(1 + \epsilon_0^2)}{(1 + \epsilon_0 B_0)^2} - \frac{2(B_0 - \epsilon_0)^2}{(1 + B_0^2)(1 + \epsilon_0 B_0)^2} \frac{1 - e^{-t_0}}{t_0},$$

(59)

where the dimensionless parameters are

$$\epsilon_0 = \frac{\epsilon}{k}, B_0 = \frac{B}{\gamma}, t_0 = \frac{2t}{(1 + \epsilon_0 B_0) (1 + B_0^2)}$$

(60)

with $\tau = \gamma / k$ and the stability condition becomes $1 + \epsilon_0 B_0 > 0$. It monotonically increases with $t_0$ with the minimum, $Q_W^m = 2/(1 + B_0^2)$ at $t_0 = 0^+$, which is exactly the same as the TUR lower bound in Eq. (14). This confirms the validity of our modified TUR.

Eq. (55) indicates that the work current obeys the first equality constraint in Eq. (14). In addition, it is easy to show that the second constraint in Eq. (14) is satisfied at $\epsilon_0 = B_0$, where the TUR equality should hold. From Eq. (59) with this condition, the TUR factor takes its minimum $Q_W = Q_W^m$, which is independent of $t_0$. Thus, the TUR lower bound is achieved out of equilibrium with $\epsilon_0 \neq 0$. This may be useful in inferring the entropy production by measuring current statistics [22–23], which should be more feasible in nonequilibrium.

We check our analytic results numerically by simulating the underdamped dynamics with a very small mass $m$. Using a generalized velocity-Verlet algorithm [57], we perform numerical integrations of the underdamped Langevin equation in Eq. (3) with dimensionless mass $m_0 = km / \gamma^2 = 0.001$. Numerical data are plotted in Fig. (3) (a) for several values of $\epsilon_0$ with $B_0 = 0.5$ and $k = \gamma = T = 1$. We used $10^5$ samples to evaluate the average and the variance of work as well as the average entropy production. The numerical data are in an excellent agreement with Eq. (14) with a small deviation due to finite-mass corrections. Note that $Q_W$ takes the modified TUR bound value, independent of $t_0$ at $\epsilon_0 = B_0 = 0.5$, as expected.

We also find the TUR factor for heat as

$$Q_Q = \frac{2(1 + \epsilon_0^2)}{(1 + \epsilon_0 B_0)^2} - \frac{2(1 + \epsilon_0^2)(\epsilon_0^2 - 1 - 2\epsilon_0 B_0)}{(1 + B_0^2)(1 + \epsilon_0 B_0)^2} \frac{1 - e^{-t_0}}{t_0},$$

(61)

which monotonically increases with $t_0$ for $\epsilon_0^2 - 1 - 2\epsilon_0 B_0 > 0$ and decreases for $\epsilon_0^2 - 1 - 2\epsilon_0 B_0 < 0$. Interestingly, the heat TUR factor $Q_Q$ is always larger than the work TUR factor $Q_W$ as

$$Q_Q - Q_W = \frac{1}{\epsilon_0^2 + B_0^2} \frac{1 - e^{-t_0}}{t_0} \geq 0,$$

(62)

with the equality in the $t_0 \rightarrow \infty$ limit. Thus, $Q_Q$ also satisfies the modified TUR. The equivalence of $Q_W = Q_Q$ in the $t_0 \rightarrow \infty$ limit was also reported in [34]. Numerical data for $Q_Q$ also agree with the analytic results very well, shown in Fig. (3) (b). The TUR equality can not be achieved for heat current, as the first equality constraint in Eq. (14) is not satisfied.

The TUR factor for the entropy production (also called
the entropy Fano factor $Q_S$ is
\[ Q_S = \frac{2(1 + e_0^2)}{(1 + e_0 B_0)^2} - \frac{2e_0 (e_0 - 2B_0 - e_0 B_0^2)}{(1 + e_0 B_0)^2} \frac{1 - e^{-t_0}}{t_0}, \]
which is always larger than the work TUR factor as
\[ Q_S - Q_W = \frac{2B_0^2}{1 + B_0^2} \frac{1 - e^{-t_0}}{t_0} \geq 0. \]

Thus, $Q_S$ also satisfies the modified TUR. Interestingly, all three TUR factors take the same value of $2(1 + e_0^2)/(1 + e_0 B_0)^2$ in the limit of $t_0 \to \infty$. The first equality constraint for $Q_S$ is satisfied only for $B_0 = 0$, where the friction tensor $G$ becomes proportional to $I$. As the second equality constraint of Eq. (13) is satisfied at $e_0 = B_0$, we find the TUR equality only at $B_0 = e_0 = 0$ with $Q_S = 2$.

It is also interesting to see that $\lim_{e_0 \to 0} Q_S = 2$, independent of the values of $B_0$ and $e_0$. This may hint a possibility of the short-time TUR for inferring the entropy production $\langle \xi \rangle$ even with the presence of a magnetic field. However, this does not come from the TUR equality constraint and may not hold with a nonlinear force. Figure 3(c) shows this property of $Q_S$ and the consistency between the numerical data and the analytic results.

Now, we make some remarks on near equilibrium with small $e_0$, where the TUR factors for work, heat, and the entropy production become
\[ Q_W \approx 2 - \frac{2B_0^2}{1 + B_0^2} \frac{1 - e^{-t_0}}{t_0} < 2 \] \[ Q_Q \approx 2 + \frac{2}{e_0^2 (1 + B_0^2)} \frac{1 - e^{-t_0}}{t_0} > 2 \] \[ Q_S \approx 2 - 4e_0 B_0 \left( 1 - \frac{1 - e^{-t_0}}{t_0} \right) \approx 2. \]

Even in the equilibrium limit, the work current always violates the conventional TUR for finite $t_0$, which implies that any simulation result should show a violation even with very small $e_0$ and very long $t_0$. In contrast, the heat current always satisfies the conventional TUR for small $e_0$, but its finite-$e_0$ correction is huge, implying that it is almost impossible to reach the conventional TUR lower bound in any practical simulation near equilibrium. In the case of the entropy production, the TUR factor approaches the conventional bound from below for $B_0 e_0 > 0$ and from above for $B_0 e_0 < 0$. In the limit of $t_0 \to \infty$ and $e_0 \to 0$, the TUR factor for all currents approaches 2 (the conventional TUR bound), independent of $B_0$.

Finally, we point out that a variant of the TUR including the dynamic activity for the underdamped dynamics is not useful in the overdamped limit, as the dynamic activity diverges with $m \to 0$ (see Eq. (40) in Ref. [37] for this specific example). We also note that the result from the linear response theory is not informative as the Onsager matrix is symmetric in this example [50].

VI. CONCLUSION

We present the modified TUR for the Langevin systems subject to a static magnetic field in the overdamped limit. The system is described by the overdamped Langevin equation with a non-white singularly correlated noise. By using the extended Fokker-Planck equation with a current variable in addition, we find the alternative dynamics with the conventional white noise and an alternative dynamic observable, which generates the extended distribution function equivalent to the original one.

Utilizing the Cramer-Rao inequality, we derive the modified TUR, which turns out to be surprisingly simple with one scale factor on the conventional TUR bound. This factor is given by the ratio of the reduced effective temperature of the overdamped motion to the reservoir temperature. This TUR is universal in the sense that the lower bound is independent of system parameters. We emphasize that this TUR is valid for a finite duration time and for general currents. Our modified TUR shows that the magnetic field lowers down the bound and the standard TUR is recovered without the magnetic field. From the exactly solvable models, we confirm the validity of our results. We also find that the TUR lower bound can be reached out of equilibrium with the magnetic field, which may be useful in inferring the entropy production by measuring non-entropic current statistics in nonequilibrium. We also generalize our TUR for an arbitrary initial state.

Our analysis is limited to systems with isotropic thermal reservoirs. It could be interesting to extend it to systems with anisotropic baths such as microscopic heat engines with broken time-reversal symmetry.

Appendix A: Derivation of the overdamped Langevin equation

We start from the formal solution of the underdamped equation, Eq. (3), as
\[ v(t) = \frac{1}{m} \int_{-\infty}^{t} d\tau \, e^{-\frac{\tau}{\gamma T} \mathbf{G}(t-\tau)} f(x(\tau)) + \eta_m(t) \] \[ \eta_m(t) = \frac{1}{m} \int_{-\infty}^{t} d\tau \, e^{-\frac{\tau}{\gamma T} \mathbf{G}(t-\tau)} \xi_T(\tau), \] with \( \langle \xi_T(t) \xi_T^*(t') \rangle = 2\gamma T I \delta(t - t') \).
Then, the noise-noise correlation matrix \( Z_m(t - t') = \langle \eta_m(t) \eta_m^T(t') \rangle \) can be easily obtained as

\[
Z_m(u) = \frac{T}{m} e^{-\frac{u}{m}G} \quad \text{and} \quad Z_m(-u) = Z_m^T(u) \quad \text{(A3)}
\]

for \( u > 0 \). Its Laplace transform becomes

\[
\int_0^\infty du \ e^{-su}Z_m(u) = T (msI + G)^{-1}, \quad \text{(A4)}
\]

which becomes \( TG^{-1} \) in the \( m \to 0 \) limit. Its inverse Laplace transform gives \( Z(u) = 2TG^{-1}\delta(u) \) and \( Z(-u) = Z^T(u) \) from Eq. (A3).

### Appendix B: The extended FP equation for the overdamped \( \xi \)-dynamics

We consider the \( \xi \)-dynamics in Eq. (11) and the current dynamic equation of Eq. (13). The extended equation of motion can be rewritten as

\[
\dot{q}(t) = A_q(q(t)) + B_q(q(t)) \circ \xi_q(t) \quad \text{(B1)}
\]

with

\[
q = \begin{pmatrix} x \\ \phi \\ v \end{pmatrix}, \quad A_q(q) = \begin{pmatrix} G^{-1}f(x) \\ \Lambda^T(x)G^{-1}f(x) \end{pmatrix}, \quad \xi_q = \begin{pmatrix} \xi_T(q) \\ 0 \end{pmatrix}, \quad \text{and} \quad B_q(q) = \begin{pmatrix} 1 \\ \Lambda^T(x) \end{pmatrix},
\]

where \( \dot{x} \) in Eq. (14) is replaced in terms of \( x \) and \( \xi_T \) by \( \dot{q}(t) \) and \( \xi_T(q(t)) = (2T_B/\gamma)\delta(t - t') \).

The corresponding FP operator for the Langevin equation of Eq. (11) with a Stratonovich-type multiplicative noise is well established, e.g. see the textbook [50], which yields

\[
\dot{\xi}_\phi = -\partial_{\phi}^T v + \frac{T_B}{\gamma} \left( \partial_{\phi}^T B_v(q) \right) \cdot \left( \partial_{\phi}^T B_v(q) \right)^T,
\]

with

\[
\partial_{\phi} = \begin{pmatrix} \nabla & \cdot \\ \partial_{\phi} \end{pmatrix}. \quad \text{(B3)}
\]

From Eq. (B2), we finally obtain

\[
\dot{\xi}_\phi = -\nabla^T_{\phi} G^{-1} f(x) + \frac{T_B}{\gamma} \nabla^T_{\phi} \cdot \nabla_{\phi} \quad \text{(B4)}
\]

where \( \nabla_{\phi} = \nabla + \partial_{\phi} \Lambda(x) \) is the tilted gradient operator.

We can derive the extended FP equation with the alternative dynamic observable \( \Psi \) given in Eqs. (20) and (21) for the \( \xi \)-dynamics. This new variable changes only the second component of \( A_q(q) \) by adding \( \varphi(x) \). Therefore, we find the extended FP operator for this case as

\[
\dot{\Psi} = -\nabla_{\Psi} G^{-1} f(x) + \frac{T_B}{\gamma} \nabla_{\Psi} \cdot \nabla_{\Psi} - \partial_{\Psi} \varphi(x) \quad \text{(B5)}
\]

with \( \nabla_{\Psi} = \nabla + \partial_{\Psi} \Lambda(x) \).

### Appendix C: The overdamped limit of the extended FP equation for the underdamped dynamics

We start with the extended FP equation for the underdamped dynamics and then take the overdamped (small-mass) limit to find the extended FP equation for the original \( \eta \)-dynamics. This procedure is quite similar to that for deriving the ordinary overdamped FP equation of Eqs. (9) and (10).

The underdamped equation of motion is given by Eq. (3) and the accumulated current is written as

\[
\Phi(\Gamma) = \int_0^t dt' \Lambda^T(x(t')) \cdot v(t'), \quad \text{(C1)}
\]

with a trajectory \( \Gamma = \{ x(t), v(t) | t \in (0, \tau) \} \), of which the dynamic evolution is given by

\[
\dot{\Phi}(t) = \Lambda^T(x(t)) \cdot v(t) \quad \text{(C2)}
\]

As \( v \) is a state variable in the underdamped description, the extended equation of motion including \( \Phi \) does not induce any multiplicative noise, in contrast to the overdamped \( \xi \)-dynamics. Thus, the type of stochastic calculus such as Ito and Stratonovich is meaningless for the FP operator.

Considering the underdamped equation of motion in Eq. (3) together with the above current dynamic equation, we can write the extended FP equation as

\[
\partial_t \tilde{p}(x, v, \Phi, t) = \left( \dot{\mathcal{L}}_{\text{rev, } \phi} + \mathcal{L}_{\text{irr}} \right) \tilde{p}(x, v, \Phi, t), \quad \text{(C3)}
\]

where the extended FP operator is split into the reversible and the irreversible part as

\[
\dot{\mathcal{L}}_{\text{rev, } \phi} = -\nabla^T_{\phi} \cdot v - \frac{1}{m} \nabla^T_{\phi} \cdot (f(x) - Bv) \quad \text{(C4)}
\]

\[
\mathcal{L}_{\text{irr}} = \frac{\gamma}{m} \nabla^T_{\phi} \cdot \left( v + \frac{T_B}{\gamma} \nabla_{\phi} \right) \quad \text{(C5)}
\]

with \( \nabla_{\phi} = \nabla + \partial_{\phi} \Lambda(x) \), the velocity gradient operator \( \nabla_v \), and the magnetic-field matrix \( B = G_a \) (the antisymmetric part of \( G \)). For convenience, we include the Lorentz term \( (Bv) \) in the reversible operator.

Note that the information of the current variable \( \Phi \) is fully contained in the tilted position gradient operator \( \nabla_{\phi} \) in the exactly same way as in the overdamped case (Appendix B). Hence, we can easily expect that the overdamped (small-mass) limit of the extended FP equation should be the same as that for the ordinary FP equation of Eqs. (9) and (10), except for replacing \( \nabla \) by \( \nabla_{\phi} \), which is presented in Eq. (18).

For completeness, we briefly sketch the standard procedure for the small-mass expansion [32, 40, 44]. The strategy is to find a series expansion of the distribution \( \tilde{p}(x, v, \Phi, t) \) in terms of the orthonormal basis of the irreversible operator \( \mathcal{L}_{\text{irr}} \). Then, the extended FP equation provides a hierarchy of coupled differential equations for
the expansion coefficients known as the Brinkman’s hierarchy \[40, 58\]. In the small-mass limit, most of higher-order coefficients can be neglected in this expansion and the overdamped extended FP equation can be rather easily obtained.

First, it is convenient to rotate the operator \( \mathcal{L}_{\text{irr}} \) in a Hermitian form by introducing
\[
\tilde{\mathcal{L}}_{\text{irr}} = (\sqrt{p^{ss}(v)})^{-1} \mathcal{L}_{\text{irr}} \sqrt{p^{ss}(v)} \tag{C6}
\]
with
\[
p^{ss}(v) = \frac{m}{2\pi T} \exp\left[ -\frac{m}{2T} |v|^2 \right], \tag{C7}
\]
which is the steady-state solution of \( \mathcal{L}_{\text{irr}} \), satisfying \( \mathcal{L}_{\text{irr}} p^{ss}(v) = 0 \).

In terms of the classical analogue of the bosonic ladder operators
\[
a_\pm = \frac{1}{2} \sqrt{\frac{m}{T}} v \mp \sqrt{\frac{T}{m}} \nabla_x, \tag{C8}
\]
the rotated operator is written as
\[
\tilde{\mathcal{L}}_{\text{irr}} = -\frac{\gamma}{m} a^T_+ \cdot a_-, \tag{C9}
\]
which is reminiscent of the Hamiltonian of the quantum harmonic oscillator. Its orthonormal eigenfunctions \( \tilde{\psi}_{n_1, n_2}(v) \) are well known with two quantum numbers \((n_1, n_2)\), which are simply related to each other by the raising and lowering ladder operators, \(a_\pm\). The ground-state eigenfunction is given as \( \tilde{\psi}_{0,0}(v) = \sqrt{p^{ss}(v)} \). It is useful to consider the same rotation on the reversible operator \( \tilde{\mathcal{L}}_{\text{rev}, \Phi} \) as
\[
\tilde{\mathcal{L}}_{\text{rev}, \Phi} = -\sqrt{\frac{T}{m}} \hat{\nabla}_\Phi \cdot a_- - \sqrt{\frac{T}{m}} \left( \hat{\nabla}_\Phi - \frac{f(x)}{T} \right) \cdot a_+ - \frac{1}{m} a^T_+ B a_- \tag{C10}
\]

The FP equation \( C9 \) can be rewritten in terms of the rotated operators as
\[
\partial_t \tilde{p}(x, v, \Phi, t) = (\tilde{\mathcal{L}}_{\text{rev}, \Phi} + \tilde{\mathcal{L}}_{\text{irr}}) \tilde{p}(x, v, \Phi, t), \tag{C11}
\]
with the transformed distribution
\[
\tilde{p}(x, v, \Phi, t) = (\tilde{\psi}_{0,0}(v))^{-1} \tilde{\psi}(x, v, \Phi, t). \tag{C12}
\]
We expand \( \tilde{p}(x, v, \Phi, t) \) in terms of the orthonormal eigenfunctions as
\[
\tilde{p}(x, v, \Phi, t) = \sum_{n_1, n_2=0}^{\infty} \tilde{C}_{n_1, n_2} \tilde{\psi}_{n_1, n_2}(v) \tag{C13}
\]
with the expansion coefficient \( \tilde{C}_{n_1, n_2} = \tilde{C}_{n_1, n_2}(x, \Phi, t) \). By putting this expansion form into Eq. \( C11 \) and focussing on the lower-order terms for small \( m \) \[39\], we find
\[
\partial_t \tilde{C}_{0,0} = -\sqrt{\frac{T}{m}} \hat{\nabla}_\Phi \cdot \tilde{C}_1, \tag{C14}
\]
\[
G \tilde{C}_1 = -\sqrt{mT} \left( \hat{\nabla}_\Phi - \frac{f(x)}{T} \right) \tilde{C}_{0,0} + O(m) \tag{C15}
\]
with \( \tilde{C}_1 = (\tilde{C}_{1,0} \tilde{C}_{0,1}) \).

The overdamped extended distribution \( \tilde{\rho}(x, \Phi, t) \) is obtained by integrating out the velocity variable of \( \tilde{p}(x, v, \Phi, t) \). Using Eqs. \( C12 \) and \( C13 \) with the orthogonality property of the eigenfunctions, we find
\[
\tilde{C}_{0,0} = \tilde{\rho}_0(x, \Phi, t). \tag{C16}
\]
Combining Eqs. \( C14 \) and \( C15 \), we find the overdamped extended FP operator as
\[
\tilde{\mathcal{L}}_{\eta, \Phi} = -\hat{\nabla}_\Phi G^{-1} \left( f(x) - T \nabla_x \right). \tag{D1}
\]

### Appendix D: Stochastic thermodynamics for the \( \eta \)-dynamics

In this appendix, we develop the stochastic thermodynamics for the \( \eta \)-dynamics. As the noise \( \eta \) has a singular character in the noise-noise correlation, the framework of the stochastic thermodynamics should be reexamined. Thus, we start from the underdamped dynamics where the stochastic thermodynamics is well established.

1. **FP operator and probability distribution**

The underdamped FP equation with the Lorentz force is
\[
\partial_t p(x, v, t) = (\mathcal{L}_{\text{rev}} + \mathcal{L}_{\text{irr}}) p(x, v, t), \tag{D1}
\]
where the ordinary FP operators \( \mathcal{L}_{\text{rev}} \) and \( \mathcal{L}_{\text{irr}} \) are given in Eqs. \( C4 \) and \( C5 \) with the replacement \( \hat{\nabla}_\Phi \) by \( \nabla \). With the same series expansion, we finally get the same equations as Eqs. \( C14 \) and \( C15 \) for the expansion coefficients \( C_{n_1, n_2}(x, t) = \int d\Phi \tilde{C}_{n_1, n_2}(x, \Phi, t) \), again by replacing \( \hat{\nabla}_\Phi \) with \( \nabla \). As we have
\[
p_\eta(x, t) = \int dv \ p(x, v, t) = C_{0,0} \tag{D2}
\]
and
\[
J_\eta(x, t) = \sqrt{\frac{T}{m}} C_1 = G^{-1} \left( f(x) - T \nabla_x \right) p_\eta(x, t) \tag{D3}
\]
then the overdamped FP operator becomes
\[
\mathcal{L}_\eta = -\nabla^T G^{-1} \left( f(x) - T \nabla \right). \tag{D4}
\]
The underdamped distribution for the small-mass limit is obtained from the expansion like in Eq. \((\ref{metric})\)

\[
p(x, v, t) \approx \psi_{0.0}(v) \left[ C_{0,0} \psi_{0.0}(v) + C_1^T \cdot \left( \psi_{1.0}(v) + \cdots \right) \right] \\
\approx p^\text{ss}(v) \left[ p_\eta(x, t) + \frac{m}{T} J_\eta(x, t) \cdot v + \cdots \right] \\
\approx p_\eta(x, t) \left( \frac{m}{2 \pi T} \right)^{\frac{1}{2}} \exp \left[ -\frac{m}{2T} (v - \frac{J_\eta(x, t)}{p_\eta(x, t)})^2 \right],
\]

where we used the eigenfunction relations as \(\psi_{1.0}(v) = v_1 \sqrt{mT} \psi_{0.0}(v)\) and \(\psi_{0.1}(v) = v_2 \sqrt{mT} \psi_{0.0}(v)\). As expected, the average local velocity \(\langle \dot{x} \rangle\) where we used \(J_\eta(x, t) = \int dv \cdot p_\eta(x, v, t)\). This form is approximate probability distribution form near the overdamped limit is also valid for the normal \(\xi\)-dynamics.

2. average current and entropy production

The average current of Eq. \((\ref{current})\) is calculated as

\[
\langle \dot{\Psi} \rangle = \int dx dv \ A^T(x) \cdot v \ p(x, v, t) \\
= \int dx A^T(x) \cdot J_\eta(x, t),
\]

where we used \(J_\eta(x, t) = \int dv \cdot v p_\eta(x, v, t)\). This form is the same as that for the normal overdamped \(\xi\)-dynamics. However, note that the probability current \(J_\eta(x, t) \neq J_\xi(x, t)\).

The total entropy production rate is given as \(\frac{m^2}{\gamma T} \int dx dv \frac{|J_{\text{int}}(x, v, t)|^2}{p(x, v, t)}\),

where the irreversible probability current is given by

\[
J_{\text{int}}(x, v, t) = -\frac{\gamma}{m} \left( v + \frac{T}{m} \nabla_v \right) p(x, v, t).
\]

Note that the Lorenz term is not included for the irreversible current, so the total entropy production here does not involve the so-called unconventional entropy production term and becomes the Clausius entropy in the steady state \(\ref{SS} \). Using the approximate distribution function in Eq. \((\ref{approx})\) for the overdamped limit, we find

\[
J_{\text{int}}(x, v, t) \approx -\frac{\gamma}{m} \frac{J_\eta(x, t)}{p_\eta(x, t)} p(x, v, t),
\]

which yields the entropy production rate in the overdamped limit as

\[
\langle \dot{S}_{\text{tot}} \rangle \approx \frac{\gamma}{T} \int dx |J_\eta(x, t)|^2 \frac{p_\eta(x, t)}{\langle \dot{S}_{\text{tot}} \rangle}.
\]

This form is also standard for the normal overdamped Langevin system with the probability current \(J_\eta(x, t)\).

3. stochastic currents

The stochastic work current done by the external force \(f_\text{ext}(x)\) is given as

\[
\dot{W}(t) = f_\text{ext}^T(x(t)) \cdot \dot{x}(t),
\]

in the underdamped dynamics. Thus, it is natural to define its overdamped \(\eta\)-dynamics as

\[
\dot{W}(t) = f_\text{ext}^T(x(t)) \cdot \dot{x}(t),
\]

which is consistent with its average in Eq. \((\ref{average})\).

The stochastic heat current dissipated into the reservoir is given as

\[
\dot{Q} = (\gamma \dot{v}(t) - \xi(t))^T \cdot \dot{x}(t),
\]

\[
= (f(x(t)) - B \dot{v}(t))^T \cdot \dot{x}(t) - \frac{d}{dt} \left( \frac{1}{2} m |\dot{v}(t)|^2 \right),
\]

where the underdamped equation of motion, Eq. \((\ref{1})\), is used. The Lorentz term vanishes due to the antisymmetric property of \(B\). The above form manifests that the heat current is not of the generic type in Eq. \((\ref{current})\). However, in the overdamped \(\eta\)-dynamics by taking the small-mass limit, the heat current becomes the generic current type of Eq. \((\ref{E29})\)

\[
\dot{Q}(t) = f_\text{ext}^T(x(t)) \cdot \dot{x}(t).
\]

The stochastic entropy production rate in the overdamped \(\eta\)-dynamics can be obtained from the system Shannon entropy production rate and the Clausius entropy production due to the heat dissipation. Taking the time derivative of the stochastic system Shannon entropy, we find

\[
\dot{S}^\text{sys}(t) = -\frac{d}{dt} \ln p_\eta(t) = -\frac{\partial p_\eta(t)}{p_\eta(t)} - \frac{\nabla^T p_\eta(t)}{p_\eta(t)} \cdot \dot{x}(t) \\
= -\frac{\partial p_\eta(t)}{p_\eta(t)} - \frac{\dot{Q}(t)}{T} + \left( \frac{G J_\eta(x(t), t))^T}{T p_\eta(t)} \right) \cdot \dot{x}(t)
\]

with \(p_\eta(t) = p_\eta(x(t), t)\). We used Eq. \((\ref{3})\) for the final equality, which yields

\[
\dot{S}^\text{tot}(t) = \dot{S}^\text{sys}(t) + \frac{\dot{Q}(t)}{T} = -\frac{\partial p_\eta(t)}{p_\eta(t)} + \frac{A_\xi^T(x(t), t) \cdot \dot{x}(t)}{T},
\]

with \(A_\xi(x(t)) = G J_\eta(x(t), t)/(T p_\eta(x(t), t))\). We note that this expression is not of the generic type for currents in Eq. \((\ref{1})\) due to the presence of the first term in the right hand side of the equation and the explicit time-dependency of the weight function. But, in the calculation of its average, the first term does not contribute and Eq. \((\ref{11})\) is easily recovered using Eq. \((\ref{12})\). Furthermore, in the steady state, the first term vanishes by definition and the weight function is time-independent as in Eq. \((\ref{12})\), thus the stochastic total entropy production rate becomes the generic type.
4. Entropy production for the ξ-dynamics

It is worthwhile to derive explicitly the stochastic entropy production rate and its average in the naive ξ-dynamics. At the first glance, one may think that the result may be trivial because the ξ-dynamics is a standard overdamped dynamics with a white Gaussian noise. It turns out to be rather subtle due to the mismatch of the asymmetric friction tensor \( \mathbf{G} \) and the symmetric diffusion matrix \( (T_B/\gamma) \mathbf{I} \). When we take the distribution equivalence \( p_\xi(t) = p_\xi(x(t), t) = p_\xi(x(t), t) \) into account, it is obvious that the time derivative of the stochastic system entropy has the same form as in Eq. (D10). Following the similar procedure as above, we get

\[
\dot{S}^{\xi}_{\text{tot}}(t) = \dot{S}^{\text{sys}}(t) + \frac{\dot{Q}(t)}{T} = -\frac{\partial_t p_\xi(t)}{p_\xi(t)} + \Lambda_{\xi}(x(t), t) \circ \dot{x}(t),
\]

where the heat dissipation rate \( \dot{Q}(t) \) is defined in Eq. (D15) and \( \Lambda_{\xi}(x(t), t) = \mathbf{G} \mathbf{J}_\xi(x(t), t)/(T p_\xi(x(t), t)) \) with the effective probability current \( \mathbf{J}_\xi(x(t), t) \) defined in Eq. (D15). From the relation between currents \( \langle \mathbf{J}_\xi(x(t), t) = J_\eta(x(t), t) \rangle \) in Eq. (51), we find that the stochastic entropy expressions for both dynamics are identical, i.e. \( \dot{S}^{\xi}_{\text{tot}}(t) = \dot{S}^{\text{tot}}(t) \).

However, its average should be different as expected from Eq. (25). In the ξ-dynamics, we find

\[
\langle \dot{S}^{\text{tot}} \rangle_\xi = \int dx \frac{(G J_\xi(x(t), t))^T}{T p_\xi(x(t), t)} \cdot J_\xi(x(t), t)
\]

\[
= \frac{\gamma}{T} \int dx \frac{|J_\xi(x(t), t)|^2}{p_\xi(x(t), t)} + \langle \nabla^T G \mathbf{A}^{-1} f \rangle_\xi
\]

\[
= \langle \dot{\Sigma} \rangle_\xi - \langle \phi S \rangle_\xi
\]

\[
= \langle \dot{S}^{\text{tot}} \rangle_\eta = \langle \dot{S}^{\text{tot}} \rangle_\eta = \langle \dot{S}^{\text{tot}} \rangle_\eta,
\]

consistent with Eq. (25).

Appendix E: Modified TUR with an arbitrary initial state

We consider a time-dependent perturbation on the force as

\[
f_{\theta}(x, t) = f(x) + \theta G J_\xi(x, \tilde{t}) \frac{p_\xi(x, \tilde{t})}{p_\xi(x, \tilde{t})}, \quad \text{with} \quad \tilde{t} = (1 + \theta)t,
\]

where the perturbation term is defined by the quantities for the unperturbed dynamics at a later time scaled by a factor of \( 1 + \theta \) with respect to the perturbed dynamics at time \( t \).

Similar to the steady-state case, we can easily show that the perturbed distribution function at \( t \) is identical to the unperturbed one at the scaled time \( \tilde{t} \), i.e. \( p_\xi(x, t) = p_\xi(x, \tilde{t}) \). This can be easily checked as the perturbed probability current with this relation

\[
J_{\xi, \theta}(x(t), t) = \left( G^{-1} f_\theta(x) - \frac{T_B}{\gamma} \right) p_\xi(x, t)
\]

\[
= J_\xi(x, \tilde{t}) + \theta \mathbf{J}_\xi(x, \tilde{t})
\]

(E2)

satisfies the Fokker-Planck equation for the perturbed dynamics

\[
\partial_t p_{\xi, \theta}(x, t) = -\nabla^T \cdot J_{\xi, \theta}(x, t),
\]

(E4)

where we used the relation \( \nabla^T \cdot J_{\xi}(x, t) = \nabla^T \cdot J_{\xi}(x, \tilde{t}) \).

It is simple to show that

\[
J_{\xi, \theta}(x(t), t) = G^{-1} (f_\theta(x(t)) - T \mathbf{V}) p_{\xi, \theta}(x(t), t) = (1 + \theta) J_\xi(x, \tilde{t}),
\]

(E5)

which yields

\[
\langle \Psi \rangle_{\xi, \theta} = \int_0^t dt' dx \, \Lambda^T(x) \cdot J_{\xi, \theta}(x, t')
\]

\[
= \int_0^{(1+\theta)t} dt' dx \, \Lambda^T(x) \cdot J_{\xi}(x, t')
\]

\[
= \int_0^{(1+\theta)t} dt' \langle \Psi(t') \rangle_\xi.
\]

(E6)

Thus, we get

\[
\lim_{\theta \to 0} \partial_\theta \langle \Psi \rangle_{\xi, \theta} = t \langle \dot{\Psi}(t) \rangle_\xi = t \langle \dot{\Phi}(t) \rangle_\eta.
\]

(E7)

Using the expression for the trajectory probability in Eq. (12) with the same initial condition for any value of \( \theta \), we can also find the Fisher information from Eq. (37) as

\[
I(\theta) = \frac{1}{2(1+\theta)} \left( \frac{\gamma}{T_B} \int_0^{(1+\theta)t} dt' dx \frac{|J_{\xi}(x, t')|^2}{p_\xi(x, t')} \right).
\]

(E8)

Setting \( \theta = 0 \) and using Eq. (51), we find

\[
I(0) = \frac{\gamma}{2T_B} \int_0^t dt' dx \frac{|J_{\xi}(x, t')|^2}{p_\xi(x, t')} = \frac{T}{2T_B} \langle \Delta S^{\text{tot}} \rangle_\eta,
\]

(E9)

where \( \langle \Delta S^{\text{tot}} \rangle_\eta \) is the total entropy production for duration time \( t \) and Eq. (D10) is used.

Finally, we have a modified TUR for the overdamped \( \eta \)-dynamics with an arbitrary initial state for a finite duration time \( t \) as

\[
\frac{\text{Var}_\eta \langle \Phi \rangle_\eta}{\langle \dot{\Phi}(t) \rangle_\eta^2} \langle \Delta S^{\text{tot}} \rangle_\eta \geq 2k_B \frac{T_B}{T},
\]

(E10)

where the Boltzmann constant \( k_B \) is restored.
Appendix F: Extension to higher dimensions

Consider a three-dimensional dynamics with a magnetic field in one direction. The two dimensional plane perpendicular to the magnetic field is spanned by the first and second component of the position vector $x$. Its third component describes the magnetic field direction. Then, the friction coefficient tensor in Eq. (4) is given by

$$ G = \begin{pmatrix} \gamma & -B & 0 \\ B & \gamma & 0 \\ 0 & 0 & \gamma \end{pmatrix} . \tag{F1} $$

The derivation procedure of the modified TUR is basically the same as before in the two-dimensional case, so we list here only the differences. The symmetric part of $G$ is given as

$$ \eta \equiv \langle \xi \rangle \equiv \frac{2D_c\delta(u)}{\gamma} \tag{F2} $$

and the naive probability current in Eq. (12) becomes

$$ J_\xi(x, t) = (G^{-1}f(x) - D_\xi \nabla)p_\xi(x, t) \tag{F3} $$

For the $\xi$-dynamics, $T_B/\gamma$ should be replaced by $D_\xi$ everywhere.

The key replacement is in the trajectory probability in Eq. (14), which yields the Fisher information as

$$ I(\theta) = \frac{1}{2} \int dx \frac{\left(\mathcal{J}_\xi(x)\right)^T D_\xi^{-1} \mathcal{J}_\xi(x)}{\overline{\Delta_\xi(x)}} \tag{F4} $$

$$ < \frac{t\gamma}{2T_B} \int dx \frac{\left|\mathcal{J}_\xi(x)\right|^2}{\overline{\Delta_\xi(x)}} \tag{F5} $$

where the third component of $|\mathcal{J}_\xi(x)|^2$ makes the inequality for $T_B < T$. As the entropy production for the $\eta$-dynamics in Eq. (33) does not change in form, we finally get the same modified TUR in Eq. (14) for three dimensions. The extensions to higher dimensions and also for arbitrary initial states are obvious. But, due to the inequality in Eq. (F5), the TUR equality cannot be attained for nonzero $B$ in three or higher dimensions.

Appendix G: Exact solutions in the solvable model

Consider the FP equation in Eqs. [3] and [10] for the $\eta$-dynamics with the linear force $f(x) = -Fx$ in Eq. [50], given as

$$ \partial_t p(x, t) = \nabla^T \cdot (Ax + D \nabla)p(x, t) , \tag{G1} $$

with the drift matrix $A = G^{-1}F$ and the asymmetric diffusion matrix $D = TG^{-1}$. We dropped the subscript $\eta$ for brevity. It is easy to show that the covariant matrix $C \equiv (xx^T) = C^T$ should satisfy

$$ AC + CA^T = D + D^T , \tag{G2} $$

in the steady state $[40, 53, 56]$. Then, we find

$$ C = \frac{\gamma T}{\gamma k + \epsilon B} I = \frac{T}{k(1 + \epsilon_0 B_0)} I , \tag{G3} $$

where the dimensionless parameters are used with $\epsilon_0 = \epsilon/k$ and $B_0 = B/\gamma$.

We consider an accumulated current $\Phi$ of the generic type in Eq. (14) with $A(x) = Jx$. The linearity in $x$ makes the exact calculation of their means and variances in the steady state rather simpler. The extended FP equation in Eqs. (17) and (15) is written as

$$ \partial_t \hat{p}(x, \Phi, t) = \tilde{\nabla}_\Phi \cdot \left( Ax + D \tilde{\nabla}_\Phi \right) \hat{p}(x, \Phi, t) , \tag{G4} $$

with the tilted gradient operator $\tilde{\nabla}_\Phi = \nabla + \partial_\Phi(Jx)$. By multiplying a function of variables and integrating out over $x$ and $\Phi$ on both sides of the extended FP equation, we can derive the dynamic equation of its average in terms of the averages of other functions. As we are interested in the steady-state average only, we take the initial condition $\hat{p}(x, \Phi, 0) = p^0(x)\delta(\Phi)$.

For the first moment of $\Phi$, we can easily obtain, through simple integrations by parts,

$$ \partial_t \langle \Phi \rangle = T \{ f \langle T \rangle \} = \Phi , \tag{G5} $$

where $\text{Tr}\{X\}$ stands for the trace of a matrix $X$. As $\Phi$ is a constant of time, we get the average accumulated current as $\langle \Phi \rangle = t\phi$. Of course, we can get the same result by integrating Eq. (16).

It is straightforward but rather involved to calculate $\langle \Phi^2 \rangle$. Here, we only sketch the calculation procedure. First, we obtain the dynamic equation for the second moment of $\Phi$ as

$$ \partial_t \langle \Phi^2 \rangle = 2 \text{Tr}\{fD^T Jt - J^T AM(t) + J^T DJC\} \tag{G6} $$

with $M(t) = \langle \Phi xx^T \rangle$. This equation contains higher moments $M(t)$ and its dynamic equation will again contain higher moments, but only 4th moments of the position variable $x$. Since $p^0(x)$ is Gaussian as in Eq. (54), the standard Wick’s theorem splits a 4th moment into a combination of second moments, which can be given by the covariant matrix $C$. Finally, the dynamic equation for $M(t)$ is given by the following closed equation,

$$ \partial_t M(t) = -AM^T(t) - M(t)A^T + \phi(C + (D + D^T)t) $$

$$ + ACJC + CJ^TCA^T . \tag{G7} $$

This is a linear differential equation for $M(t)$, so that the formal solution is given by

$$ M(t) = \phi Ct + H - E(t)HE^T(t) , \tag{G8} $$

where an auxiliary symmetric matrix $H$ is defined by the relation

$$ ACJC + CJ^TCA^T = AH + HA^T , \tag{G9} $$
and a matrix $E(t)$ is defined by

$$E(t) = e^{-At} = e^{-\frac{(k + 2\gamma)}{2\sigma^2}t} \left( \begin{array}{cc} \cos(\omega t) & -\sin(\omega t) \\ \sin(\omega t) & \cos(\omega t) \end{array} \right)$$

where the diffusion coefficient $D_\Phi$ is given by

$$D_\Phi = \text{Tr} \{ J^T (DJC - AH) \} .$$

By introducing another auxiliary symmetric matrix $K$, for convenience, such that

$$J^T A + A^T J = KA + A^T K ,$$

we finally reach the formal solution

$$\text{Var}[\Phi] = 2D_\Phi t + \text{Tr} \{ K (H - E(t)HE^T(t)) \} .$$

The formal solution allows us to obtain the variance by solving the linear equations in the elements of $H$ and $K$ provided by Eq. (G9) and (G13). By determining the auxiliary matrices for $J = W, Q,$ and $S$, we obtain the variance for work, heat, and entropy production.
