The microscopic origin of superconductivity in the high-transition-temperature (high-\(T_c\)) copper oxides remains the subject of active inquiry; several of their electronic characteristics are well established as universal to all the known materials, forming the experimental foundation that all theories must address. The most fundamental of those characteristics, for both the copper oxides and other superconductors, is the dependence of the superconducting \(T_c\) on the degree of electronic band filling. The recent report of superconductivity\(^1\) near 4 K in the layered sodium cobalt oxyhydrate, Na\(_{0.35}\)CoO\(_2\)·1.3H\(_2\)O, is of interest owing to both its triangular cobalt–oxygen lattice and its generally analogous chemical and structural relationships to the copper oxide superconductors. Here we show that the superconducting \(T_c\) of this compound displays the same kind of behaviour on chemical doping that is observed in the high-\(T_c\) copper oxides. Specifically, the optimal superconducting \(T_c\) occurs in a narrow range of sodium concentrations (and therefore electron concentrations) and decreases for both underdoped and overdoped materials, as observed in the phase diagram of the copper oxide superconductors. The analogy is not perfect, however, suggesting that Na\(_{x}\)CoO\(_2\)·1.3H\(_2\)O, with its triangular lattice geometry and special magnetic characteristics, may provide insights into systems where coupled charge and spin dynamics play an essential role in leading to superconductivity.

Like the high-\(T_c\) superconductors, the Na\(_{x}\)CoO\(_2\)·1.3H\(_2\)O crystal structure\(^1\) consists of electronically active planes (in this case, edge-sharing CoO\(_6\) octahedra) separated by layers (in this case, Na\(_{x}\)CoO\(_2\)·1.3H\(_2\)O) that act as spacers, to yield electronic two-dimensionality, and also act as charge reservoirs (see below). We have found that varying the Na content in Na\(_{x}\)CoO\(_2\)·1.3H\(_2\)O results in the same type of out-of-plane chemical doping control of in-plane electronic

**Figure 1** Powder X-ray diffraction patterns (Cu K\(_{α}\) radiation) for Na\(_{x}\)CoO\(_2\)·H\(_2\)O samples prepared using different concentrations of the bromine de-intercalant. Inset, an enlargement of the 006 reflections for each sample, highlighting the shift in the layer spacing as a function of sodium content. The Na\(_{x}\)CoO\(_2\)·H\(_2\)O samples were prepared by chemically de-intercalating sodium from Na\(_{0.7}\)CoO\(_2\) using bromine as an oxidizing agent. Na\(_{0.5}\)CoO\(_2\) (0.5 g) was stirred in 20 ml of a Br\(_2\) solution in acetonitrile at room temperature for five days. Bromine concentrations representing substoichiometric (0.5x), stoichiometric (1x), and molar excess (10-100x) relative to sodium content were employed. (1x) indicates that the amount of Br\(_2\) used is exactly the amount that would theoretically be needed to remove all of the sodium from Na\(_{0.7}\)CoO\(_2\). The product was washed several times with acetonitrile and then water, and then dried briefly under ambient conditions. The sodium content of the phases was determined by the inductively coupled plasma atomic emission spectroscopy (ICP-AES) method. Very high Na diffusion coefficients facilitate homogenization of the Na contents of the samples at ambient temperature.
charge that is found for the copper oxide superconductors. This is achieved by changing the Br concentration used in the de-intercalation of the host material. (See Fig. 1 legend for the synthesis procedure). Powder X-ray diffraction (XRD) patterns for the synthesized samples are shown in Fig. 1. The bromine-treated samples made with stoichiometric (0.5X; see Fig. 1 legend for definition of this nomenclature) and substoichiometric (0.5X) bromine solutions consist primarily of a partially de-intercalated, anhydrous, non-superconducting Na$_x$CoO$_2$ phase ($c \approx 11.2$ Å). A small amount of the hydrated superconducting phase Na$_x$CoO$_2$·1.3H$_2$O ($c \approx 19.6$ Å) is detectable by XRD for the 1X sample. Single phase, superconducting, fully hydrated Na$_x$CoO$_2$·1.3H$_2$O occurs for higher Br concentrations, with a small amount of Na$_x$CoO$_2$ in the 10X sample. Chemical analysis indicates that the sodium content of the resulting materials generally varies systematically in the samples prepared in different Br concentrations, over a range of $x = 0.26$ to 0.45 (Table 1).

Thermogravimetric analysis of all the samples on very slow heating in oxygen (Fig. 2 inset) showed that their behaviour was identical to that reported previously for Na$_{0.25}$CoO$_2$·yH$_2$O (ref. 2). The interlayer ‘crystal water’ content remains essentially constant, at approximately 1.3 per formula unit, despite differences in sodium content in the single phase samples. The intergran water is variable from sample to sample, as is to be expected. Figure 1 shows a noticeable shift in the positions of the 00l reflections for the fully hydrated Na$_x$CoO$_2$·1.3H$_2$O phases, yielding a systematic variation in the $c$ axes of the unit cells (Table 1) from 19.43 Å for the $x = 0.45$ sample to 19.77 Å for the $x = 0.26$ sample. This increase in layer separation with decreasing sodium content for the hydrated superconducting phase is similar to that observed in the dehydrated Na$_x$CoO$_2$ phase$^{3,4}$. The $a$ axis, reflecting the in-plane CoO$_6$ dimensions, is independent of Na content within the precision of our measurements.

Zero field cooled d.c. magnetization data measured in a field of 5 Oe for selected samples are shown in the main panel of Fig. 2. The magnetizations at 1.8 K represent approximately 100% of the theoretical value expected for perfect diamagnetism. Such strong diamagnetic signals provide evidence for bulk superconductivity. Na concentration inhomogeneities in the samples are probably the primary source of rounding of the superconducting transitions. An important point revealed by the data in Fig. 2 is that $T_c$ for each sample is clearly different, indicating that differences in sodium content significantly affect the superconductivity of Na$_x$CoO$_2$·1.3H$_2$O.

In order to characterize fully the dependence of $T_c$ on sodium content, we used a.c. susceptibility, which is more sensitive to weakly superconducting samples. Figure 3 shows the a.c. susceptibility for all the Na$_x$CoO$_2$·yH$_2$O samples. For the multiple phase $x = 0.45$ and $x = 0.40$ samples, the $T_c$ values are approximately 2.0 K (Table 1), and the diamagnetic a.c. signals are very small, consistent with their phase analysis by XRD, which shows primarily non-superconducting, anhydrous Na$_x$CoO$_2$. In the $x = 0.40$ sample, the fully hydrated Na$_x$CoO$_2$·1.3H$_2$O phase accounts for approximately 15% of the sample, allowing us to estimate the maximum sodium content of the Na$_x$CoO$_2$·1.3H$_2$O phase to be approximately $x = 0.35$. The data suggest that at its highest possible Na content, the Na$_x$CoO$_2$·1.3H$_2$O phase has a $T_c$ near 2 K.

All other samples are single phase sodium cobalt oxide with the crystal structure of the superconductor. The $x = 0.32$ and $x = 0.33$ samples yield slightly higher $T_c$ values (between 2.1 and 2.2 K) and signals that are one to two orders of magnitude higher than the multiple phase $x = 0.40$ sample. Single phase samples with sodium contents of $x = 0.32, 0.30$ and 0.29 display superconducting

---

**Table 1 Characterization of Na$_x$CoO$_2$·yH$_2$O**

| Sodium content ($x$) | Bromine concentration (0.5X) | $a$ axis (Å) | $c$ axis (Å) | $T_c$ (K) |
|----------------------|-------------------------------|-------------|-------------|-----------|
| 0.45                 | 0.5 X                         | N/A         | N/A         | 2.0       |
| 0.40                 | 1 X                           | 2.823(3)    | 19.43(2)    | 2.0       |
| 0.32                 | 10 X                          | 2.823(2)    | 19.52(2)    | 2.1       |
| 0.33                 | 20 X                          | 2.823(2)    | 19.58(1)    | 2.2       |
| 0.32                 | 30 X                          | 2.823(2)    | 19.58(1)    | 3.0       |
| 0.30                 | 40 X                          | 2.823(2)    | 19.69(2)    | 4.3       |
| 0.29                 | 100 X                         | 2.819(3)    | 19.77(2)    | 4.0       |
| 0.26                 | 50 X                          | 2.821(2)    | 19.77(2)    | 2.4       |

Na$_x$CoO$_2$·yH$_2$O was prepared by bromine de-intercalation and hydration of Na$_x$CoO$_2$.

* Sodium content determined by ICP-AES. The estimated error of analysis is ±0.02 per formula unit.

† Determined by least squares refinement of powder XRD data, from 6–10 reflections between 2θ values of 5° and 60°.

‡ $T_c$ determined from the a.c. susceptibility data, from the extrapolation of the steepest slope of the $M$ versus $T$ curve in Fig. 3 to $M = 0$. 

---

**Figure 2** Zero field cooled d.c. magnetization for superconducting samples of Na$_x$CoO$_2$·1.3H$_2$O. Data were obtained for $x = 0.29, 0.30$ and 0.32, using a Quantum Design PPMS magnetometer. $H_{dc} = 5$ Oe. Inset, loss in weight of single phase Na$_x$CoO$_2$·1.3H$_2$O ($x = 0.26$ and 0.32) samples heated extremely slowly in O$_2$ (0.25 degrees per minute) illustrating the method by which we distinguish the amount of crystal water (the higher-temperature weight loss) from the intergran water (the lower-temperature weight loss). The change in weight that occurs on loss of crystal water is seen to be essentially the same in both low-Na and high-Na content materials.

**Figure 3** Zero-field cooled a.c. magnetization for all superconducting Na$_x$CoO$_2$·yH$_2$O samples. $H_{ac} = 3$ Oe, $H_{dc} = 5$ Oe, $f = 10$ kHz. Magnetization data for the weakly superconducting samples $x = 0.45$ and 0.40 are shown in the inset.
Tc values of 3.0 K, 4.3 K and 4.0 K, respectively (Fig. 3). Significantly, the single phase sample with x = 0.26 has a Tc of only 2.4 K.

Figure 4 shows, in the main panel, the superconducting phase diagram of Na_{x}CoO_{2-y}H_{2}O. The variation of Tc with x indicates that there is an optimal sodium composition for the occurrence of superconductivity, x = 0.30. Tc decreases at both lower and higher Na contents. As the sodium content increases between x = 0.26 and x = 0.35, the formal oxidation state of the Co decreases from 3.74+ to 3.65+, and the optimum for superconductivity is 3.70+. This variation of Tc with the degree of electronic doping of the CoO2 planes, is analogous with the behaviour observed in the copper oxide superconductors. We note that the synthesis method we have employed, and other ambient temperature synthesis methods that might be used in this system, are likely to result in a distribution of sodium contents for each sample. If ideally uniform sodium samples can be prepared, we expect that the superconducting ‘dome’ shown in Fig. 4 may become more narrow in sodium content.

Preliminary correlation of the chemical doping due to the Na content and the true electronic doping state of the CoO2 planes can be accomplished by electron counting in the context of electronic analogies to the copper oxides hold. In this scenario, then, each added Na above x = 0.3, represents the addition of 0.3 electrons to the half-filled band per formula unit. Values of x less than 0.3 would then represent underdoped materials, and values of x greater than 0.3 would represent overdoped materials. More detailed characterization of the electronic state of the triangular cobalt oxides will be needed to determine just how closely the electronic analogies to the copper oxides hold.

This work reveals several experimental findings that are critical for understanding the superconductivity of Na_{x}CoO_{2-y}H_{2}O. The discovery of a maximum in Tc as a function of the Na content establishes the optimal chemical doping level for superconductivity. A fundamental similarity between the layered copper oxide and layered cobalt oxide superconductors is seen in the decrease in Tc for both the underdoped and overdoped materials. The optimal doping level for superconductivity is clearly higher with respect to the Mott–Hubbard-like half-filled two-electron band in Na_{x}CoO_{2-y}H_{2}O (+0.3 electrons) than in the copper oxides (+0.15 electrons or holes). This may either reflect a fundamental difference between the two types of superconductors, or the influence of as-yet unknown structure–electronic state correlations in the cobalt oxides. Observations of unusual electrical transport properties in the host material Na_{x}CoO_{2-y}CoO2 suggest that coupled spin and charge dynamics may be implicated in the superconductivity, although there are significant differences from copper oxide systems10,11.

Observations that the lower hydrates with closer CoO2–CoO2 interplanar distances are not superconducting above 2 K (ref. 2), and that Tc decreases under pressure12, indicate that the two-dimensional character of the structure is important. Though the intrinsically complex materials chemistry of the Na_{x}CoO_{2-y}H_{2}O superconductor makes it difficult to characterize, we believe that potentially fruitful comparisons to the copper oxides, and the fact that this compound may represent the literal embodiment of Anderson’s original proposal for the resonating valence bond state13, make it worthy of further study.
