ABSTRACT

The Luminous Infrared Galaxy NGC 1614 hosts a prominent circumnuclear ring of star formation. However, the nature of the dominant emitting mechanism in its central ~100 pc is still under debate. We present sub-arcsecond angular resolution radio, mid-infrared, Paα, optical, and X-ray observations of NGC 1614, aimed at studying in detail both the circumnuclear ring and the nuclear region. The 8.4 GHz continuum emission traced by the Very Large Array and the Gemini/T-ReCS 8.7 μm emission, as well as the Paα line emission, show remarkable morphological similarities within the star-forming ring, suggesting that the underlying emission mechanisms are tightly related. We used a Hubble Space Telescope/NICMOS Paα map of similar resolution to our radio maps to disentangle the thermal free–free and non-thermal synchrotron radio emission, from which we obtained the intrinsic synchrotron power law for each individual region within the central kiloparsec of NGC 1614. The radio ring surrounds a relatively faint, steep-spectrum source at the very center of the galaxy, suggesting that the central source is not powered by an active galactic nucleus (AGN), but rather by a compact (r ≲ 90 pc) starburst (SB). Chandra X-ray data also show that the central kiloparsec region is dominated by SB activity, without requiring the existence of an AGN. We also used publicly available infrared data to model-fit the spectral energy distribution of both the SB ring and a putative AGN in NGC 1614. In summary, we conclude that there is no need to invoke an AGN to explain the observed bolometric properties of the galaxy.

Key words: galaxies: individual (NGC 1614) – galaxies: nuclei – galaxies: starburst – infrared: galaxies – radio continuum: galaxies – supernovae: general

1. INTRODUCTION

Luminous Infrared Galaxies (LIRGs; 1011 ≤ LIR/L⊙ ≤ 1012; LIR = L[8–1000 μm]) are known to closely follow the far-infrared (FIR) to radio correlation, and hence must host either a burst of star formation, or an active galactic nucleus (AGN) at their center, or both. Disentangling whether an AGN or a starburst (SB) is the dominant heating mechanism is essential to understand the role of the IR-phase in galaxy evolution (see, e.g., Alonso-Herrero et al. 2012, 2013). The central kiloparsec regions of LIRGs are heavily enshrouded in dust, which prevents their study at optical wavelengths. Fortunately, at infrared wavelengths the extinction is significantly lower than in the optical, and radio is essentially extinction-free, which permits the study of the innermost regions of LIRGs, if the required spatial resolution is available. Also, sub-arcsecond imaging with Chandra allows to image the inner central regions of LIRGs, thanks to the penetrating power of X-rays. Therefore, high-angular (sub-arcsecond) resolution observations of local (D ≲ 100 Mpc) LIRGs at infrared, radio, and X-rays can be efficiently used to disentangle a putative AGN from an SB.

NGC 1614 (IRAS 04315-0840) is a galaxy merger in a late stage of interaction, with strong tidal tails and only one obvious nucleus, though there is evidence for the remnant of a secondary nucleus (Alonso-Herrero et al. 2001). Recently, several authors have suggested that the ring is formed by an inner Lindblad resonance, where the gas is driven to it through the dust lanes (Olsson et al. 2010; König et al. 2013). The existence of an AGN at the center of NGC 1614 is still a matter of debate: Risaliti et al. (2000) classified the hard X-ray emitting source in the...
central region of the galaxy as an AGN. However, the low signal-to-noise detection of the power-law (PL) continuum makes its interpretation uncertain (Olsson et al. 2010). Sub-millimeter array observations of NGC 1614 seem to indicate a nuclear, non-thermal component, but which cannot be ascribed solely to an AGN, or to an SB (Wilson et al. 2008). Yuan et al. (2010) have classified NGC 1614 as an SB–AGN composite (albeit with a significantly larger contribution from the SB), using their new optical classification scheme. More recently, Väisänen et al. (2012) have used 3.3 μm spatially resolved polycyclic aromatic feature (PAH) imaging and continuum diagnostics to argue that an obscured AGN can be ruled out, concluding that NGC 1614 is a pure SB.

In this paper, we present sub-arcsecond angular resolution radio (3.6 and 6 cm), mid-IR (8.7 μm), optical (0.4 and 0.8 μm), and Chandra X-ray images of the central kiloparsec region of NGC 1614 to study in detail the central kiloparsec region of this LINIRG. Our main aim is to shed light on the AGN/SB controversy existing in the literature, as well as to discuss the striking morphological similarities between the radio and mid-IR images, which suggest a common origin for both emission mechanisms.

2. OBSERVATIONS AND DATA REDUCTION

In this section, we describe our sub-arcsecond resolution radio (3.6 cm), mid-IR (8.7 μm), PAH (3.3 μm), Paα (1.9 μm), and optical (0.4 and 0.8 μm) observations of NGC 1614, which show striking morphological similarities (see Figure 1), as well as Chandra X-ray data and multi-epoch, archival VLA data at 3.6 and 6 cm, aimed at characterizing the spectral index of the nucleus and the star-forming (SF) ring, as well as to study its variability (see Figures 3 and 5). In Table 1, we show the log for the radio and infrared observations discussed in this paper.

2.1. Radio

We observed NGC 1614 on 2004 November and 2006 May using the Karl G. Jansky VLA in A configuration at 3.6 cm (project code AC749), in full polarization mode. The total synthesized bandwidth was 100 MHz. We used 3C 48 as the absolute flux density calibrator, and 0420-014 (R.A. (J2000.0) = 04h23m15s801; decl. (J2000.0) = −01°20′33″07′′), at an angular distance of 7′.7 from NGC 1614, for phase-calibration purposes. We used the NRAO AIPS package for all data reduction steps, including amplitude and phase calibration, as well as imaging. We imaged the source using a pixel size of 0′05 and applied a natural weighting scheme, which resulted in a final synthesized beam of 0′042 × 0′025 at a position angle of −33°8: for the observations on 2004, and a very similar one for the 2006 observations (0′041 × 0′024; −28°4:7). We used our VLA image on 2004 as the reference one, to compare with the infrared images. For this, we increased the pixel size of our radio images up to 0′089.

To study the variability of the circumnuclear region in NGC 1614, we also used publicly available VLA continuum data of NGC 1614 in A configuration obtained in 1986 May (project code AN37) at 6.0 cm, and in 1999 July (project code AL503) at 3.6 and 6.0 cm. We reduced these data in an analogous manner to that previously described for the 3.6 cm data. We also used the same absolute flux density and phase calibrators mentioned above, thus ensuring that the astrometry was close to the milliarcsecond level. We obtained our images in the same manner, using an automatic script to prevent any systematic errors. In all cases, we used a natural weighting scheme for the u–v data in the imaging process, using each time the same pixel size and convolving synthesized beam. The off-source rms noise attained in the final images was in good agreement with the expected theoretical thermal noise.

2.2. Infrared

We made use of the Gemini/T-ReCS 8.7 μm imaging data presented by Díaz-Santos et al. (2008), observed on 2006 September 16–30, using the T-ReCS instrument on the Gemini South telescope with a plate scale of 0′089 pixel−1, with a total on-source integration time of 1680 s. We refer the reader to Díaz-Santos et al. (2008) for a detailed description of the observations and data reduction.

We also used Paα observation obtained in 1998 February with the NICMOS camera on board the Hubble Space Telescope (HST), using the filter F190N on NIC2, with a plate scale of 0′076 pixel−1, and centered at 1.89 μm, for a total on-target time of 640 s, presented in Alonso-Herrero et al. (2001). A nearby filter (F187N) was used to remove the stellar continuum. We refer the reader to Alonso-Herrero et al. (2000, 2001) for details on the data reduction.

Finally, we made use of UIST Integral Field Unit observations on UKIRT performed in 6 and 2009 January 26, at 3.3 μm with...
Figure 1. Multi-wavelength comparison of the nuclear region of NGC 1614. The top panels show radio (left) and mid-IR (right). The central panels show continuum-subtracted Paschen \( \alpha \) (left) and the 3.3 \( \mu \)m PAH feature (right). The bottom panels show HST/ACS images at 0.4 \( \mu \)m (left) and 0.8 \( \mu \)m (right), \( B \) (F435W) and \( I \) (F814W) filters, respectively. Based on the radio emission, we have defined seven regions to compare the images, including the nuclear region (N), the whole ring (R), and the total area (T). Note the close similarity in the star formation ring and the contrast in the nuclear region between the radio and mid-IR wavelengths. Pixel sizes are the same for all images, except for the PAH feature map. Color scales are independent. See Figure 2 in Díaz-Santos et al. (2008) for a mid-IR/Pas ratio image. (A color version of this figure is available in the online journal.)

2.3. Optical

We used publicly available optical images of NGC 1614 taken in 2006 with the Advanced Camera for Surveys (ACS) camera on board the HST. In particular, we retrieved broadband images with filters F435W (centered at 4328.2 Å \( \sim 0.4 \mu \)m, \( \sim B \) band)
and F814W (centered at 8057.0 Å $\sim 0.8 \mu m$, $\sim I$ band). The pixel size of these images corresponds to 0"0.049 pixel$^{-1}$.

We reduced the images using the on-the-fly HST pipeline, applying the highest quality reference files that were available at the time of retrieval. The calibrated F435W image had only few cosmic rays remaining. However, the F814W image was severely contaminated with cosmic rays, which were removed as explained in Miralles-Caballero et al. (2011).

### 2.4. X-Rays

We used publicly available archival data of NGC 1614 from ACIS-S on board Chandra, taken on 2012 November 21. The pixel scale is 0"0.49 pixel$^{-1}$, and the spectral range covers from 0.2 to 10 keV. We used the CXC Chandra Interactive Analysis of Observations software package (CIAO14), version 4.3, for the data reduction, which was made in the same way as described in Hernández-García et al. (2013).

We extracted a nuclear spectrum of NGC 1614 from a 3′′ aperture circular region centered at R.A. = $4^{h}34^{m}00^{s}$, decl. = $-8^{\circ}34^{\prime}45^{\prime\prime}$ (J2000.0). We extracted the background spectrum from a 5′′ aperture source-free circular region, in the same chip as the target, and close to the source, to minimize effects related to the spatial variations of the CCD response.

### 2.5. Image Alignment and Estimation of Flux Density Uncertainties

We aligned the images by taking as reference position the flux density peak of the innermost region of our reference radio image (3.6 cm map from 2004 November), and then shifted the peaks of our 8.7 $\mu$m and Pa$\alpha$ images so as to make them coincide with the radio peak with an estimated uncertainty of 0″04. The 3.3 $\mu$m PAH map was aligned by matching the corresponding strong 3–4 $\mu$m continuum nucleus to the nucleus seen in the 8.7 $\mu$m and Pa$\alpha$ maps with an estimated uncertainty of 0″05.

For the optical HST images, which did not show a clear morphological correlation with the radio or infrared images, we used reference images at the intermediate wavelengths of 1.1 $\mu$m and 1.6 $\mu$m. The resulting images are shown in Figure 1. Table 1 shows the astrometric shift applied to the images with respect to the VLA astrometry.

To estimate the uncertainty in the (integrated) flux densities obtained for any given region, we used the following equation, which takes into account both thermal noise and systematic uncertainties,

$$\sigma \simeq \sqrt{N_b \times \text{rms}^2 + (\eta \times S_{\text{int}})^2},$$

(1)

where \text{rms} is the off-source root mean square of the image; \eta is a factor that accounts for uncertainties in the calibration system (we used $\eta = 0.03$ for the VLA radio images and $\eta = 0.10$ for the optical and IR images, which are conservative values); $S_{\text{int}}$ is the integrated flux of the region of interest; and $N_b$ corresponds to the number of beams that fits into a given region (the number of pixels in that region) for the radio (optical/IR) images.

### 3. RESULTS AND DISCUSSION

#### 3.1. Radio and Infrared Images

We show in Figure 1 our 3.6 cm continuum VLA image of NGC 1614 from 2004 November and the 8.7 $\mu$m continuum T-ReCS image at similar angular resolution. We also show the HST/NICMOS continuum-subtracted Pa$\alpha$ image for comparison. The outer circle in the images covers essentially all of the emission at each wavelength and has a radius of $\sim$780 pc. We identify five regions within the circumnuclear ring: A, B, C, and D, which correspond to areas of strong emission, and N, which roughly delimits the nuclear region ($r \lesssim 90$ pc). For convenience, Figure 1 shows two additional regions: R, which corresponds to the whole ring, and T, which encompasses the entire region (ring and nucleus, R+N). We show the locus and size for each of those regions, as well as their integrated 3.6 cm, 8.7 $\mu$m, 3.3 $\mu$m, and Pa$\alpha$ fluxes in Table 2.

The most conspicuous feature is the prominent mid-IR emission of the nucleus, N, which contrasts with its rather faint emission at radio wavelengths (see Figure 1 and Table 2). The regions to the northwest of the ring, A and B, show a mid-IR/radio ratio below the average of the whole ring (R), while regions C and D show the opposite behavior.

Figure 2 shows the azimuthal profiles at all three wavelengths, starting from the central pixel (the brightest pixel in region N for the 3.6 cm and 8.4 $\mu$m images) and toward eight cardinal directions, separated by 45° from each other. To adequately compare the profiles, we normalized the radio continuum and Pa$\alpha$ fluxes to the median of the ratios (8.7 $\mu$m/3.6 cm) of each region for the case of the mid-IR image, and to the median of the ratios (Pa$\alpha$/3.6 cm) for the Pa$\alpha$ image. We therefore increased the values of the 3.6 cm and Pa$\alpha$ values by factors of 19.26 and 10.79, respectively, which allows to see more clearly variations in the whole circumnuclear region.

---

### Table 2

Regions of Enhanced Radio and IR Emission in NGC 1614 and Their Integrated Fluxes

| Region | Center (J2000) | Diameter (arcsec) | Diameter (pc) | Pa$\alpha$ (mJy) | 3.3 $\mu$m (mJy) | 8.7 $\mu$m (mJy) | 3.6 cm (mJy) |
|--------|---------------|------------------|--------------|----------------|----------------|----------------|--------------|
| A      | 00:010s, 44′55 | 0.40             | 124          | 1.9 ± 0.2      | 1.5 ± 0.2      | 21 ± 2         | 1.41 ± 0.05  |
| B      | 59:990s, 45′11 | 0.86 ± 0.41      | 266 × 127    | 3.9 ± 0.4      | 3.5 ± 0.4      | 44 ± 4         | 2.95 ± 0.12  |
| C      | 00:030s, 45′70 | 0.40             | 124          | 2.2 ± 0.2      | 1.5 ± 0.2      | 19 ± 2         | 0.96 ± 0.04  |
| D      | 00:070s, 45′12 | 0.40             | 124          | 2.5 ± 0.3      | 1.4 ± 0.2      | 22 ± 2         | 1.07 ± 0.04  |
| N      | 00:027s, 45′12 | 0.60             | 186          | 4.3 ± 0.4      | 3.6 ± 0.4      | 49 ± 5         | 1.70 ± 0.08  |
| T      | 00:027s, 45′12 | 2.50             | 773          | 47.1 ± 4.7     | 45.9 ± 4.6     | 799 ± 80       | 26.49 ± 2.20 |
| R      | 00:027s, 45′12 | T–N              | 42.8 ± 4.3   | 42.3 ± 4.3     | 750 ± 75       | 24.78 ± 2.10  |

Notes. Coordinates are given with respect to 4h34m, −8°34′. Region B is an ellipse with a position angle of 0°, for which we give major and minor axes. Region R is the ring defined by subtracting region N from total region T. The Pa$\alpha$ values are continuum-subtracted. The radio fluxes correspond to the image from 2004 November, used as the reference radio image throughout the paper.

---

http://cxc.harvard.edu/ciao4.3/
Overall, the same trend is also center up to the outermost regions of the SF ring, as found emission follow almost exactly the same trend from the very PAH feature (3.3 μm, in cyan), starting from the center of the images. Radio, Paα, and PAH fluxes are scaled up by the median of the 8.7 μm/3.6 cm, 8.7 μm/Paα, and 8.7 μm/3.3 μm ratios, respectively (factors 19.2, 10.8, and 13.6). The profile is shown for eight cardinal directions, with an azimuthal binning of the size of a pixel (0′′.116 for the 3.3 μm image and 0′′.089 for the other cases). The shaded area, from 0.3 to 1.0 arcsec, corresponds to the approximate width of the star formation ring. (A color version of this figure is available in the online journal.)

Table 3

| Region | 6.0 cm | 3.6 cm | Spectral Index |
|--------|--------|--------|---------------|
|        | 1986 (mJy) | 1999 (mJy) | 2004 (mJy) | 2006 (mJy) | Average | Non-thermal |
| A      | 1.40 ± 0.06 | 1.46 ± 0.05 | 1.29 ± 0.05 | 1.26 ± 0.04 | 1.23 ± 0.04 | -0.48 ± 0.06 | -0.56 ± 0.10 |
| B      | 3.42 ± 0.12 | 3.71 ± 0.11 | 3.09 ± 0.10 | 3.01 ± 0.09 | 2.88 ± 0.09 | -0.53 ± 0.17 | -0.72 ± 0.16 |
| C      | 1.15 ± 0.05 | 1.23 ± 0.04 | 0.91 ± 0.04 | 1.00 ± 0.03 | 0.97 ± 0.03 | -0.74 ± 0.04 | -1.44 ± 0.13 |
| D      | 1.22 ± 0.06 | 1.13 ± 0.04 | 0.98 ± 0.04 | 1.08 ± 0.04 | 1.00 ± 0.04 | -0.62 ± 0.03 | -1.14 ± 0.22 |
| N      | 2.57 ± 0.10 | 2.81 ± 0.09 | 1.85 ± 0.07 | 1.79 ± 0.06 | 1.79 ± 0.06 | -0.68 ± 0.13 | -1.30 ± 0.53 |
| T      | 34.06 ± 1.06 | 35.70 ± 1.08 | 25.61 ± 0.79 | 26.39 ± 0.80 | 25.45 ± 0.77 | -0.73 ± 0.25 | -1.19 ± 0.63 |
| R      | 31.48 ± 0.98 | 32.89 ± 0.99 | 23.77 ± 0.73 | 24.60 ± 0.74 | 23.66 ± 0.72 | -0.73 ± 0.25 | -1.18 ± 0.63 |

Notes. Both images at 6.0 cm were mapped with a beam of 0.71 × 0.43 arcsec and the three epochs at 3.6 cm with a beam of 0.50 × 0.36 arcsec. The (two-point) spectral index was obtained for the 6.0 and 3.6 cm simultaneous observations of NGC 1614 carried out in 1999. Column 7 shows the average spectral indices obtained directly from the spectral index map, while Column 8 spectral indices are obtained from the isolated non-thermal emission (see main text for details).

Figure 2 also shows that both the continuum 8.7 μm and Paα emission follow almost exactly the same trend from the very center up to the outermost regions of the SF ring, as found by Díaz-Santos et al. (2008). Overall, the same trend is also seen when comparing the IR azimuthal profiles against those of the radio continuum. The remarkable morphological similarities seen at both radio and mid-infrared wavelengths in most regions of the circumnuclear ring strongly suggest that the mechanisms responsible for that emission must be related. König et al. (2013) show a similar plot (see their Figure 6), with the azimuthal profile of the CO (2–1) and Paα emission displayed together with the radio emission at three different bands. The peaks of radio and mid-infrared emission in the ring would pinpoint then the regions where most of the SB activity has taken place in the last 10–20 Myr. The 8.7 μm mid-IR flux includes both warm dust continuum and PAH emission. The PAH emission is known to vary quite significantly from one SF region to another, or one galaxy to another, depending on the exact physical conditions (see, e.g., Calzetti et al. 2007; Díaz-Santos et al. 2010).

There are morphological differences between the 3.3 μm PAH feature map and the rest of the IR and radio images. Imanishi & Nakanoishi (2013) have suggested that either an age differentiation, or different dust extinction between the regions may explain those differences.

Olsson et al. (2010) ascribed the radio emission at 3.6 and 6.0 cm from NGC 1614 mainly to free–free emission from H II regions (mainly due to massive stars). As we shall show in the next sections, the non-thermal contribution from core-collapse supernovae (CCSNe) and supernova remnants (SNRs) is also significant within the circumnuclear ring, implying the existence of young SBs in the ring of NGC 1614.

3.2. Radio Variability and Spectral Index of the Circumnuclear Ring in NGC 1614

In SF regions, non-thermal radio emission and variability are usually good tracers of recently exploded supernovae (SNe). We show in Figure 3 the radio interferometric images of NGC 1614 at 6.0 cm (epochs 1986 and 1999) and 3.6 cm (epochs 1999, 2004 and 2006), obtained with the VLA in A configuration, and imaged using the same restoring beam at all epochs for consistency. In Table 3, we show the integrated flux for each defined region and for each epoch.
The images at each wavelength look overall similar, and the total radio emission at 3.6 and 6.0 cm has not varied among the epochs, within the uncertainties. In fact, while there seems to be an apparent increase of the flux density between 1986 and 1999 at 6 cm (see Figure 3, top panel) for several regions, including N and B (the brightest spot in the circumnuclear ring), this variability is not quantitatively significant ($\lesssim 1\sigma$, see Table 3) and hence we cannot claim they are real. Similarly, the images at 3.6 cm between 1996 and 2006 (Figure 3, bottom panel) suggest that the flux density in region B has been steadily decreasing from 1996 till 2006, while region C would have experienced a rise and decrease of flux density during this period, possibly indicating SN activity. Again, the variations are not significant, and unfortunately we lack further observations that could have allowed us to confirm, or rule out, those variations. We note, however, that the peaks of the regions sometimes show significant changes from epoch to epoch, suggesting that SN events may be occurring. Still, it seems that no very radio bright, Type IIn SN ($L_{v,\text{peak}} \gtrsim 10^{52}$ erg s$^{-1}$ Hz$^{-1}$) has exploded in NGC 1614 during the 1986–2006 period. Such bright SNe are known to evolve slowly and stay bright for $\gtrsim 10$ yr, e.g., SN 1986D in NGC 891 (Pérez-Torres et al. 2002), or some of the SNe in the compact nuclear SBS of Arp 299-A (Pérez-Torres et al. 2009b; Bondi et al. 2012) and Arp 220 (Parra et al. 2007; Batejat et al. 2011). However, we cannot exclude completely the possibility of a Type IIn SN having exploded and be missed by us, given the scarcity of the radio observations.

We used the quasi-simultaneous 3.6 and 6.0 cm observations in 1999 to derive the average spectral index $\alpha$ ($S_{v} \propto v^{\alpha}$) for each of the regions defined in Figures 1 and 3. The values in col. 7 of Table 3 result from obtaining an average value of each region from the spectral index map created with the actual observations at 6.0 and 3.6 cm from 1999 (which are the combination of the thermal free–free and non-thermal synchrotron radio emission), while Column 8 shows the intrinsic synchrotron radio spectral index, once the thermal component is subtracted from the total radio emission (see Section 3.5 for details). The overall non-thermal spectral index for both the ring and the total area is $\alpha \simeq -1.2$. Such steep spectral index is suggestive of most of the diffuse, extended synchrotron radio emission being due to SNe and SNRs. Note, however, that the brightest regions in the ring have spectral indices significantly flatter than $-1.2$, which might suggest that the synchrotron radio emission is mostly powered by SNRs, rather than by recently exploded SNe.

The [Fe II] emission line at 1.26 and 1.64 $\mu$m has also been proposed as a tracer of the SN rate in nearby SB galaxies (see, e.g., Moorwood & Oliva 1988; Greenhouse et al. 1991; Colina & Perez-Olea 1992; Colina 1993; Vanzi & Rieke 1997; Alonso-Herrero et al. 2003), both in a pixel-by-pixel basis and as an integrated approach. The [Fe II] 1.26 $\mu$m emission in NGC 1614 shows a $C$-shape morphology in the circumnuclear SP ring (Rosenberg et al. 2012), with the brightest emitting region matching approximately region D in our 3.6 and 6.0 cm images, i.e., an apparent anti-correlation between the maxima in the continuum VLA radio emission and the [Fe II] 1.26 $\mu$m. However, after correcting for extinction in the [Fe II] image, this anti-correlation disappears (M. J. F. Rosenberg 2013, private communication).
3.3. Spatially Resolved X-Ray Emission

We fitted the Chandra spectrum using standard procedures within the X-ray software XSPEC\textsuperscript{15} version 12.7.0. We fitted the data using four different models: (1) a pure thermal model (MEKAL), where the thermal emission is responsible for the bulk of the X-ray energy distribution; (2) an absorbed PL model, which corresponds to a non-thermal source representing an AGN; (3) a composite of a thermal plus an absorbed PL model (MEPL); and (4) a thermal model with tuned individual abundances (VMEKAL), which models the metal abundance pattern of type II SNe (see, e.g., Iwasawa et al. 2011; Zaragoza-Cardiel et al. 2013). In all models, we kept fixed the Galactic absorption to the predicted value using the tool ftools (Dickey & Lockman 1990; Kalberla et al. 2005).

Neither the MEKAL nor the PL models yielded satisfactory fits to the data. The MEPL model fitted the data well, but with a physically unrealistic PL index of $\Gamma = 3.1$. Using an MEPL model to fit XMM-Newton data (with a circular aperture of $\sim 15''$), Pereira-Santaella et al. (2011) obtained a luminosity four times higher with $\Gamma = 2$. Our best fit turned out to be the VMEKAL, which is shown in Figure 4, together with the soft and hard X-ray maps. This model finds abundances for Mg xii (1.36 keV), Si xiii (1.85 keV), and S xvi (2.4 keV). The corresponding luminosity in the soft band for this model is log $L(0.5-2 \text{ keV}) = 40.78^{+0.04}_{-0.05}$ erg s$^{-1}$, while there are not enough counts in the hard band to derive a realistic value for the luminosity. The fitted temperature is $kT = 1.7 \pm 0.7$ keV.

3.4. Thermal Free–Free and Non-thermal (Synchrotron) Radio Emission

The bulk of the continuum radio emission observed in the central region of NGC 1614 comes from its circumnuclear ring (Figure 1), where a strong burst of star formation is ongoing (Alonso-Herrero et al. 2001). Massive stars and their associated H II regions would be responsible for the thermal free–free radio emission, while SNe and SNRs would account for the non-thermal synchrotron radio emission. Disentangling the contribution from each of those two components is non-trivial from radio measurements alone, since it would require observations at several frequencies in the range from $\sim 20$ cm down to $\lesssim 1$ cm, and ideally with the same angular resolution, which is not our case.

Here, we estimate the expected thermal free–free continuum radio emission from extinction-corrected Pa$\alpha$ measurements. Then, using our (extinction-free) continuum radio data at 3.6 cm from 2004 November, we infer the amount of radio emission that is of non-thermal, synchrotron origin. As a bonus, from the Pa$\alpha$ measurements we obtain one of the most relevant physical parameters in the SB in NGC 1614, namely, its Lyman photon ionizing flux, $N_{\text{ion}}$, which is used in Section 3.5 to compare with the value derived from the spectral energy distribution (SED) fitting of the SB in the circumnuclear region of NGC 1614. In fact, using standard relations (see Colina et al. 1991) and the Pa$\alpha$ to H$\alpha$ recombination ratio and assuming no photon leakage, we can derive the ionizing photon flux, $N_{\text{ion}}$, as

$$N_{\text{ion}} = 6.27 \times 10^{12} L_{\text{Pa}\alpha} \text{s}^{-1}, \quad (2)$$

where $N_{\text{ion}}$ is measured in photons s$^{-1}$ and $L_{\text{Pa}\alpha}$ is the Pa$\alpha$ extinction-corrected luminosity, in erg s$^{-1}$. From our continuum-subtracted Pa$\alpha$ image, we obtain a flux density of $\sim 47.1$ mJy for the emission of the whole region, T, which corresponds to an absorbed $L_{\text{Pa}\alpha} = 3.6 \times 10^{21}$ erg s$^{-1}$. This luminosity translates into an (absorbed) ionizing photon flux of $N_{\text{ion}} \approx 2.27 \times 10^{54}$ s$^{-1}$. To obtain the relevant, unabsorbed ionizing photon flux, we corrected for the extinction, $A_V$. Fortunately, the extinction toward NGC 1614 is well studied, and is in the range $A_V = 3-5$ (see, e.g., Neff et al. 1990; Puxley & Brand 1994; Alonso-Herrero et al. 2001; Kotilainen et al. 2001; Rosenberg et al. 2012). Assuming a value of $A_V = 4$, and using our observed Pa$\alpha$, we obtain the unabsorbed Pa$\alpha$ flux by using standard H$\alpha$ recombination lines ratios, for Case B (Baker & Menzel 1938), and using

$$\frac{F(\lambda)}{I(\lambda)} = 10^{-C(\text{H}\beta) [f(\lambda)+1]}, \quad (3)$$

\textsuperscript{15} http://heasarc.gsfc.nasa.gov/xanadu/xspec/
where \( F(\lambda) \) and \( I(\lambda) \) are the absorbed and unabsorbed fluxes, respectively, \( C(H\beta) \) is the reddening coefficient, and \( f(\lambda) \) is the reddening function (Cardelli et al. 1989). The resulting unabsorbed \( \text{Pa}_\alpha \) flux is \( \approx 80.2 \text{ mJy} \), corresponding to an unabsorbed ionizing photon flux of \( N_{\text{ion}} \approx 3.87 \times 10^{54} \text{s}^{-1} \).

Using standard relations between \( \text{Pa}_\alpha \) and \( \text{H} \beta \) (e.g., Osterbrock 1989) and Equation (3) from Condon (1992), we can obtain the thermal continuum radio emission as

\[
S_{\text{thermal}} = 1.076 \times 10^{13} \times F(\text{Pa}_\alpha) \nu^{-0.1},
\]

with \( S_{\text{thermal}} \) in mJy, the unabsorbed \( \text{Pa}_\alpha \) flux, \( F(\text{Pa}_\alpha) \), in erg cm\(^{-2}\) s\(^{-1}\), and \( \nu \) in GHz, and where we have assumed for simplicity a temperature of 10,000 K and \( N_e = 10^8 \text{ cm}^{-3} \), which are typical of compact (i.e., size \( \lesssim 1 \text{ pc} \)) SB regions. (The uncertainty in our estimates is dominated by the plasma electron temperature, since \( S_{\text{thermal}} \propto T_e^{0.52} \). A value of \( T_e = 20,000 \text{ K} \) would result in a thermal continuum radio flux \( \sim 23\% \) higher.) In this way, we isolated the thermal and non-thermal contributions to the radio emission, which are shown in Table 4 and in Figure 5. The corresponding thermal free–free radio flux density is 11.03 mJy at 3.6 cm for the whole region, T, and is about 42\% of the total 3.6 cm radio emission in the central regions of NGC 1614. Since our \( \text{Pa}_\alpha \) measurements are much less affected by extinction than optical measurements, our decomposed values have a much weaker dependence on the actual value of the extinction. Indeed, allowing for an extinction \( A_V \) in the range (3–5), results in thermal free–free radio flux densities in the range (9.65–12.60) mJy.

In summary, we obtained the thermal radio emission from a scaled version of the \( \text{Pa}_\alpha \) image, and the non-thermal radio emission as the result of the subtraction of the thermal emission from the total radio emission at 3.6 cm from 2004 November. The ratio of thermal free–free to synchrotron radio emission can be used as an indicator of the SB age of each region in the circumnuclear ring of NGC 1614. Regions where there is essentially no synchrotron radio emission imply that SNe have not yet started to explode, indicating ages of at most \( \sim 4 \text{ Myr} \), while regions where the SNe have already started to explode would be older. The models of Perez-Olea & Colina (1995) provide a quantitative estimate of the thermal free–free emission from massive stars, and non-thermal radio continuum emission from SNe and SNRs. The ratios of thermal to non-thermal radio emission (see Table 4 and Figure 5) for regions A and B are about \( \sim 0.5 \), while those of regions C and D of 1.1 and 1.2, respectively. The ratios above (and the free–free thermal continuum luminosities) can be well explained if the emission in regions C and D come from instantaneous bursts with ages \( \lesssim 5.5 \text{ Myr} \), where SNe have only recently started to explode. On the other hand, the emission from regions A and B would come from slightly older (\( \sim 8 \text{ Myr} \)) bursts, where essentially all

![Figure 5. Decomposition of the 3.6 cm flux from 2004 November of the central region of NGC 1614 into thermal (left panel, scaled version of the \( \text{Pa}_\alpha \) applying an uniform extinction of \( A_V = 4 \)) and non-thermal (middle panel, thermal radio emission subtracted from the total radio flux) components. The right panel shows the relative contribution of the thermal emission. Note that regions A and B are dominated by synchrotron non-thermal emission, in contrast with regions C and D. (A color version of this figure is available in the online journal.)](image)

| Region | \( S_{\text{th}} \) (mJy) | \( S_{\text{syn}} \) (mJy) | \( L_{\text{th}} \) (10\(^{27} \text{ erg s}^{-1} \text{ Hz}^{-1} \)) | \( L_{\text{syn}} \) (10\(^{27} \text{ erg s}^{-1} \text{ Hz}^{-1} \)) | \( \text{Unabs.} L_{\text{Pa}_\alpha} \) (10\(^{20} \text{ erg s}^{-1} \text{ Hz}^{-1} \)) | \( N_{\text{ion}} \) (10\(^{53} \text{s}^{-1} \)) |
|--------|----------------|----------------|----------------|----------------|----------------|----------------|

| T      | 11.03          | 15.47          | 54.03          | 75.79          | 62.07          | 38.92          |
| R      | 10.01          | 14.77          | 49.07          | 72.41          | 56.37          | 35.34          |

Notes. Column 1: region name; Column 2: thermal fraction of the flux at 3.6 cm (obtained as a scaled version of the \( \text{Pa}_\alpha \) image assuming a constant extinction of \( A_V = 4 \)); Column 3: synchrotron fraction of the flux at 3.6 cm, (obtained as Column 1 subtracted from the total radio emission); Column 4: thermal radio luminosity at 3.6 cm; Column 5: synchrotron radio luminosity at 3.6 cm; Column 6: unabsorbed \( \text{Pa}_\alpha \) luminosity; Column 7: number of ionizing photons.
exploding SNe come from stars with masses in the $20–30 \ M_\odot$ range.

We note that the above discussion is valid at 3.6 cm and is made under the assumption of a constant extinction of $A_V = 4$ and variations across the ring may affect the thermal to non-thermal ratios. In fact, there seems to exist a gradient of the extinction increasing toward the west, as shown in Figure 1 of König et al. (2013). Considering an extinction of $A_V = 5$ for regions A and B, and $A_V = 3$ for regions C and D, we still obtain thermal to non-thermal radio emission ratios of $\sim 0.6$ for regions A and B, $\sim 0.7$ for region C, and $\sim 0.8$ for region D.

The images of the decomposed radio emission help to understand the apparent paradox of the prominent mid-IR emission of the nucleus, N, which shows rather faint emission at radio wavelengths (see Figure 1 and Table 2). Since the thermal free–free emission is directly proportional to the Pa$\alpha$ flux, the decomposed images would indicate that the radio emission from the nuclear region is dominated by thermal free–free emission (for any $A_V$ in the range 3–5), which in turn suggests it is powered by an SB, rather than an AGN, as we show in Section 3.6.

In the absence of low-frequency absorption, we would expect that the emission at lower frequencies (e.g., 21 cm) should be dominated by synchrotron emission, in contrast to the 3.6 and 6.0 cm images, where the contribution of the thermal emission is relevant. In fact, when we scale the non-thermal emission at 3.6 cm (Figure 5) to 21 cm, using our derived non-thermal spectral indices (see Table 3), one would expect to recover the emission from the MERLIN image at 21 cm shown in Figure 4 in Olsson et al. (2010). Although the extrapolated image correlates, in general terms, well with the Olsson et al. image, all regions of NGC 1614, except regions A and N, show at 21 cm a lower flux density than expected, with the radio emission from region D being especially suppressed. This should not come as a surprise, as those SB regions have many massive stars that create big H$\text{II}$ regions around them. Those H$\text{II}$ regions are very efficient low-frequency absorbers, as demonstrated by, e.g., the large emission measure (EM) values in the vicinities of SN2000ft in the circumnuclear SB of NGC 7469 (Alberdi et al. 2006; Pérez-Torres et al. 2009a), or around SN A0 in Arp 299A (Pérez-Torres et al. 2009b). Indeed, the low-frequency absorption implies that region D, the one showing the least flux density at 21 cm, has an EM $\approx 1.2 \times 10^7$ cm$^{-6}$ pc, a value very similar to that found for the in the vicinities of SNe SN 2000ft in NGC 7469, or A0 in Arp 299A. Regions B and C have moderate EM values ($\approx 3.3, 4.7 \times 10^6$ cm$^{-6}$ pc). Finally, regions A and N have negligible EM values and essentially their radio emission is not being efficiently suppressed at low frequencies. While a discussion of the specific reasons for the differences in the low-frequency absorption displayed by the circumnuclear regions of NGC 1614 is beyond the scope of this paper, we just note here that our results are in agreement with all regions being synchrotron dominated at 21 cm, but whose emission is being significantly suppressed in some regions by low-frequency absorption that is most likely due to foreground absorbers, i.e., H$\text{II}$ regions. The main exceptions are regions A and N, which seems to suffer very little low-frequency absorption, possibly due to a smaller density in those region, as indicated by the low EM values.

### 3.5. The Star Formation and Core-collapse Supernova Rates in NGC 1614

The main goal of this section is to determine two of the most important parameters of any SB, which are its star formation rate (SFR) and its CCSN rate. The (constant) CCSN rate, $v_{\text{CCSN}}$, can be related to the (constant) SFR as follows (Pérez-Torres et al. 2009a):

$$v_{\text{CCSN}} = \text{SFR} \left( \frac{\alpha - 2}{\alpha - 1} \right) \left( \frac{m_{\text{SN}} - m_{\text{SN}^{-1}}}{m_{\text{SN}}^{-1} - m_{\text{SN}}} \right),$$

where SFR is the (constant) SFR in $M_\odot$ yr$^{-1}$, $m_1$ and $m_u$ are the lower and upper mass limits of the initial mass function ($\Phi \propto m^{-\alpha}$), and $m_{\text{SN}}$ is the minimum mass of stars that yield SNe, assumed to be $8 M_\odot$ (e.g., Smartt 2009). Mattila & Meikle (2001) found an empirical relationship between $L_{\text{IR}}$ and $v_{\text{CCSN}}$: $v_{\text{CCSN}} \approx 2.7 \times 10^{-12} (L_{\text{IR}}/L_\odot)$ yr$^{-1}$. This implies a CCSN rate for the circumnuclear SB of NGC 1614 of $\approx 1.08$ SN yr$^{-1}$, for $L_{\text{IR}} \approx 4.0 \times 10^{11} L_\odot$, which according to Equation (5) corresponds to a (constant) SFR of $\approx 52.9 M_\odot$ yr$^{-1}$. However, a constant star formation process is likely to be, for LIRGs in general and for NGC 1614 in particular, a poor approximation to the actual SB scenario (Alonso-Herrero et al. 2001).

The opposite case to a constant SFR is that of a single instantaneous SB. For example, Rosenberg et al. (2012) used Starburst 99 (Leitherer et al. 1999) to model the emission of NGC 1614 within an instantaneous SB scenario, and obtained an average age for the SB of 6.4 Myr and an integrated SN rate of 0.9 yr$^{-1}$. U et al. (2012) found an SFR of $\text{SFR_{UV+IR}} \approx 51.3 M_\odot$ yr$^{-1}$. Alonso-Herrero et al. (2001) modeled the star formation of NGC 1614 using two Gaussian bursts, each of them with a FWHM of 5 Myr, separated by 5 Myr, obtaining an age of $\approx 11$ Myr after the peak of the first burst, i.e., a total age of $\approx 16$ Myr. From the extinction-corrected [Fe ii], they predicted an SN rate of 0.3 SN yr$^{-1}$.

An intermediate approach is that of an exponentially decaying SB, which is the approach we have followed here. Namely, we modeled the near-IR to sub-millimeter SED of NGC 1614 by combining pure SB models from Efstathiou et al. (2000), with those of Efstathiou & Siebenmorgen (2009), and models for the host galaxy. The latter models the emission from the stars using the models by Bruzual & Charlot (2003) and the emission from diffuse (circus) dust using the model of Efstathiou & Siebenmorgen (2009). The fit is shown in Figure 6, where photometric data points were obtained from NED, 16 Soifer et al. (2001), Skrutskie et al. (2006), and Ishihara et al. (2010).

The best-fit SB model parameters are quoted in Table 5. It yields a bolometric luminosity of $10^{11.39} L_\odot$, an initial SFR of 85.1 $M_\odot$ yr$^{-1}$ (57.7 $M_\odot$ yr$^{-1}$ averaged over the duration of the SB), a CCSN rate of 0.43 SN yr$^{-1}$, and an ionizing photon flux of $3.47 \times 10^{54}$ s$^{-1}$.

---

3.6. Is There an AGN in the Center of NGC 1614?

The nuclear region, N, shows a non-thermal spectral index of $\alpha \sim -1.80$. Such a steep spectral index seems to be at odds with an AGN origin for the radio emission of region N, but can be reconciled with the scenario of a compact SB, powered by SNe and SNRs. While such a high value of $\alpha$ is not rare or extreme for SBs (see, e.g., NGC 253 in Heesen et al. 2011), it implies heavy synchrotron losses and, given the large radiation field in the nuclear region (see the prominent 8.7 $\mu$m continuum and Paα line emission), also large inverse Compton losses. We note that the radio spectral index is the average value over region N, of $\sim$90 pc in radius, so in principle we cannot rule out completely the existence of a hidden AGN inside that region, as found in other LIRGs, e.g., in Arp 299-A (Pérez-Torres et al. 2010). However, even if there is an AGN, its radio luminosity would not contribute more than $\sim$6% and $\sim$7.6% at 3.6 and 6.0 cm, respectively (see Table 3). For comparison, the AGN in Arp 299-A, as found from very long baseline interferometry (VLBI) observations, has a 5.0 GHz flux density at centimeter wavelengths of about 820 $\mu$Jy/b (Pérez-Torres et al. 2010), which corresponds to a luminosity of $v L_{v,\text{AGN}} \sim 9 \times 10^{36}$ erg s$^{-1}$ and accounts for no more than about 11% of the compact VLBI 5.0 GHz flux. This luminosity value is also less than 1% of the total 5.0 GHz emission, as traced by eMERLIN within the region where all SNe/SNRs are exploding (see Figure 4 and Section 3.3 in Bondi et al. 2012). The corresponding 5.0 GHz luminosity of a putative AGN in NGC 1614 is therefore no more than $v L_{v,\text{AGN}} \sim 7.1 \times 10^{37}$ erg s$^{-1}$ and, if most of this luminosity comes in turn from a nuclear SB, the AGN must be even fainter.

The ratio of the 8.7 $\mu$m/Paα emission also suggests that region N is powered by a burst of star formation. In fact, the ratio in the central $\sim$90 pc agrees well with the ratios obtained for nuclei of H II systems, and is significantly lower than obtained for the nuclei of Sy/Sy 2 systems (Table 3 in Díaz-Santos et al. 2008), which are known to host an AGN.

Similarly, the Chandra X-ray emission supports an SB driven scenario for the central regions of NGC 1614. We calculated hardness ratios, which are model-independent, for different apertures. We defined the hardness ratio as $HR = (H - S)/(H + S)$, being $H$ and $S$ the hard [2.0–10.0] keV and soft [0.5–2.0] keV bands, respectively. For an aperture of 3″ in radius, we get $HR = -0.40$, while for an aperture of 0′.3 (coincident with region N) we get a significantly harder spectrum, $HR = +0.69$. The point at which HR becomes positive (i.e., the hard emission dominates) is $\lesssim 0′.4$. The weak hard X-ray emission could easily be due to the presence of X-ray binaries in a compact SB in the central 0′.3 (i.e., $\sim 110$ pc), in agreement with the sizes of the SBs seen in, e.g., Arp 299-A (Pérez-Torres et al. 2009a; Bondi et al. 2012) and Arp 220 (Parra et al. 2007). While we cannot rule out completely that an AGN makes also some contribution, the presence of emission lines of Mg xii, Si xiii and S xiv in the spectrum (see Figure 4) suggests the existence of SNe and/or SNRs. Although the temperature is somewhat higher than expected for SNe, with typical values of $kT = 0.5$ keV (see, e.g., Soría & Wu 2003), they are in good agreement with values obtained for young SNe (e.g., SN2001gd in NGC 5033 had $kT = 1.1$ keV; Pérez-Torres et al. 2005).

Additionally, using the multi-wavelength optical, radio, and soft X-rays diagnostic diagram from Pérez-Olea & Colina (1996), region N would be in the SB dominated region, as can be seen in Figure 7, with log($L_X/L_{5GHz}$) = 4.77 and log($L_X/L_{H\alpha}$) < -0.43. (The inequality accounts for the fact that the radio and Hα luminosity are for region N, while the X-ray luminosity corresponds to a 3″ aperture.)

We also used archival data from Spitzer Infrared Spectrograph (IRS) to check the high-resolution spectra for NGC 1614 looking for [Ne v] lines at 14.3 and 24.3 $\mu$m, which would be indicative of the existence of an AGN (Genzel et al. 1998; Armus et al. 2007), but found no evidence of their presence.

Finally, we also fitted the multi-wavelength SED with a combination of SB models and AGN torus models (Efstathiou & Rowan-Robinson 1995) and found that the contribution of the AGN to the total bolometric luminosity, if any, would be at most $\sim 10%$. In summary, all evidence shows that the bulk of the observed emission (at all wavelengths) from the circumnuclear region of NGC 1614 is powered by a burst of star formation. In fact, the starburst contribution (dashed red), and the host galaxy contribution (dot-dashed green).

(A color version of this figure is available in the online journal.)
NGC 1614 can be explained with the existence of a powerful SB, without any need to advocate the existence of an AGN.

4. SUMMARY

We have presented sub-arsecond angular resolution radio, mid-infrared, optical, and X-ray observations of the central kiloparsec region of NGC 1614. Our main results are as follows.

1. The continuum emission of the circumnuclear ring, as traced by 3.6 cm VLA, T-ReCS 8.7 μm and HST/NICMOS Paα show remarkable morphological similarities, suggesting a common origin for both radio, mid-IR, and hydrogen recombination line emission in the ring, likely recent SF activity along the ring.

2. The analysis of multi-epoch VLA observations at 3.6 and 6.0 cm spanning almost 20 yr show that the total radio luminosity of the ring is quite stable, and the possible variations are not significant. Still, if such variability was real, it could be ascribed to CCSN activity, since the luminosities involved in them ($L_v \sim (1.0-1.5) \times 10^{37} \text{erg s}^{-1} \text{Hz}^{-1}$), are typical of Type IIb/IIl SNe. The steady radio emission of NGC 1614 is rather high in the whole circumnuclear ring, likely due to significant thermal free–free emission from massive stars and H II regions, as well as to diffusion of synchrotron emission produced in the shocks of SNe and SNRs.

3. From the Paα image of the circumnuclear ring, we measured the ionizing photon flux for the ring and the nucleus, and predicted the (thermal) free–free radio emission. We then estimated, from our radio images, the intrinsic non-thermal synchrotron contribution to the observed radio continuum. We find that the circumnuclear (radio) ring surrounds a faint and compact ($r \lesssim 90$ pc) source at the very center of the galaxy, with a non-thermal steep spectrum ($\alpha_{\text{syn}} \simeq -1.3$), suggesting that the central source is not powered by an AGN, but rather by a compact SB. In any case, a putative AGN would contribute at most $\sim 8\%$ to the total radio luminosity.

4. We have modeled the X-ray spectrum of the central 3 kpc region of NGC 1614, using Chandra X-ray data. This region is well described by a pure thermal model with $kT \sim 1.7$ keV, with the presence of lines indicative of SNe/SNRF. The circumnuclear region has a hardness ratio $HR \simeq -0.40$, in good agreement with expectations for a SB, while the inner $\sim 0\farcs4$ ($\sim 120$ pc) of NGC 1614 shows $HR \simeq 0.69$, which could be explained by a population of high-mass X-ray binaries.

5. We also have used several diagnostic diagrams, which suggest that region N (the nuclear region) has no AGN inside (e.g., Perez-Olea & Colina 1996; Asmus et al. 2011) and is dominated by an SB.

6. Finally, we have used publicly available infrared data to perform a model-fit to the spectral energy distribution of NGC 1614. We find that the circumnuclear SF region in NGC 1614 can be well described by an exponentially decaying burst that started $\lesssim 30$ Myr, and which has an average CCSN rate of $\sim 0.4$ SN yr$^{-1}$ and an average SFR of $\sim 58 \ M_\odot$ yr$^{-1}$.

In summary, although a dust-enshrouded AGN cannot be completely ruled out by our observations, there is no need to advocate its existence, since the SB completely dominates the observed properties of both the circumnuclear SF ring and the nuclear region. We have proposed deep, dual-frequency, contemporaneous VLBI observations, which will unambiguously show whether or not there is a faint AGN sitting at the very center of NGC 1614.

We thank the anonymous referee for constructive comments which helped to improve our paper. We are grateful to Alba Fernández-Martín and Josefa Masegosa for useful discussions, and to Tanio Díaz-Santos for his help with the Paα images of NGC 1614.
