ABSTRACT

It is well known that the long-term evolution of the photospheric magnetic field plays an important role in building up free energy to power solar eruptions. Observations, despite being controversial, have also revealed a rapid and permanent variation of the photospheric magnetic field in response to the coronal magnetic field restructuring during the eruption. The Helioseismic and Magnetic Imager instrument (HMI) on board the newly launched Solar Dynamics Observatory produces seeing-free full-disk vector magnetograms at consistently high resolution and high cadence, which finally makes possible an unambiguous and comprehensive study of this important back-reaction process. In this study, we present a near disk-center, GOES-class X2.2 flare, which occurred in NOAA AR 11158 on 2011 February 15. Using the magnetic field measurements made by HMI, we obtained the first solid evidence of a rapid (in about 30 minutes) and irreversible enhancement in the horizontal magnetic field at the flaring magnetic polarity inversion line (PIL) by a magnitude of \( \sim 30\% \). It is also shown that the photospheric field becomes more sheared and more inclined. This field evolution is unequivocally associated with the flare occurrence in this sigmoidal active region, with the enhancement area located in between the two chromospheric flare ribbons and the initial conjugate hard X-ray footpoints. These results strongly corroborate our previous conjecture that the photospheric magnetic field near the PIL must become more horizontal after eruptions, which could be related to the newly formed low-lying fields resulting from the tether-cutting reconnection.

1. INTRODUCTION

Almost two decades ago, we discovered rapid and permanent changes of vector magnetic fields associated with flares (Wang 1992; Wang et al. 1994). Specifically, the transverse field near the flaring magnetic polarity inversion line (PIL) is found to enhance substantially and irreversibly across the time duration of the flare, which is also often accompanied by an increase of magnetic shear. A similar trend indicating a more horizontal orientation of the photospheric magnetic field after flares and coronal mass ejections (CMEs) has continued to be observed later on in many observations (Wang et al. 2002, 2004, 2005; Liu et al. 2005; Wang et al. 2007; Jing et al. 2008; Li et al. 2009; Liu et al. 2011) and shows some agreement with recent model predictions (Li et al. 2011). Nevertheless, a majority of such studies are unavoidably hampered by the obvious limitations, ground-based observations (e.g., seeing variation and the limited number of observing spectral positions), probably because of which mixed results were also reported (Ambastha et al. 1993; Hagyard et al. 1999; Chen et al. 1994; Li et al. 2000a, 2000b).

On the other hand, flare-related variations in the line-of-sight (LOS) component of photospheric magnetic field have been clearly recognized (e.g., Wang et al. 2002; Spirock et al. 2002; Yurchyshyn et al. 2004; Sudol & Harvey 2005; Wang 2006; Wang & Liu 2010; Petrie & Sudol 2010). In particular, the feature of unbalanced flux evolution of opposite polarities could provide an indirect evidence for the more horizontal orientation of photospheric fields after flares/CMEs (Wang & Liu 2010). However, it is noted that the changes of the LOS field alone cannot provide complete understanding of the field restructuring (Hudson 2011).

It is notable that vector magnetic field data have been made available with the Helioseismic and Magnetic Imager (HMI) instrument (Schou et al. 2011) on board the newly launched Solar Dynamics Observatory (SDO). Its unprecedented observing capabilities give a favorable opportunity to finally resolve any uncertainties regarding the evolution of photospheric magnetic field in relation to flares/CMEs.

In this study, we investigate a near disk-center X2.2 flare on 2011 February 15, which provides the first solid evidence of the enhancement in the horizontal field at the flaring PIL using the seeing-free HMI data. We will discuss the implications of such a change in the context of magnetic reconnection model for flares.

2. OBSERVATIONS AND DATA REDUCTION

The HMI instrument obtains filtergrams in six polarization states at six wavelengths along the Fe i 6173 Å spectral line to compute Stokes parameters \( I, Q, U, V \), which are then reduced with the HMI science data processing pipeline3 to (1) retrieve the vector magnetic field using the Very Fast Inversion of the Stokes Vector (VFISV) algorithm (Borrero et al. 2010) based on the Milne–Eddington approximation, (2) resolve the \( 180^\circ \) azimuthal ambiguity using the “minimum energy” method (Metcalf 1994; Leka et al. 2009). As of the time of this writing, only AR11158 processed data have been released by the HMI team (Hoeksema & The HMI Team 2011). For our study, we use the product of vector magnetograms projected and remapped to heliographic coordinates, with a spatial resolution of \( \sim 1'' \) and a cadence of 12 minutes.

The temporal and spatial relationship between the change of the photospheric fields and flare energy release can provide important clues concerning the eruption mechanism. The evolution
of the flare hard X-ray (HXR) emission was entirely registered by the Reuven Ramaty High Energy Solar Spectroscopic Imager (RHESSI; Lin et al. 2002). PIXON images (Hurford et al. 2002) in the 35–100 keV energy range showing the flare footpoints were reconstructed using the front segments of detectors 2–8 with 16–32 s integration time throughout the event. To provide the chromospheric and coronal context, we also used Hα images taken by the Solar Optical Telescope (SOT; Tsuneta et al. 2008) on board Hinode, and EUV images made by the Atmospheric Imaging Assembly (AIA; Lemen et al. 2011) on board SDO.

3. RESULTS

The $\beta \gamma$ region NOAA 11158 was located close to the disk center ($S21^\circ, W21^\circ$) when the 2011 February 15 X2.2 flare started at 01:44 UT, peaked at 01:56 UT, and ended at 02:06 UT in GOES 1–8 Å flux. The flare was initiated at the center of the active region, where opposite magnetic flux concentrations underwent a counterclockwise-rotation-like motion possibly resulting in highly sheared fields along the PIL (Liu et al. 2011b; Sun et al. 2011). By monitoring the evolution of the horizontal field, a compact region R along the PIL (enclosed by the white bordered line) is readily identified to show a pronounced enhancement of horizontal field strength $B_h = \sqrt{B_x^2 + B_y^2}$ after the flare (cf. Figures 1(a) and(b)). Close temporal association of this field change with flare emissions and its permanence relative to the flare duration are demonstrated in Figure 2(a) covering a period spanning 10 hr, in which we find that $\langle B_h \rangle$ at region R increases by $\sim$30% from
∼1300 G to ∼1700 G in ∼30 minutes. This rapid evolution ensues from the beginning of the flare at 01:44 UT, with the change-over time cotemporal with the rapid rising of soft X-ray flux and peaking of HXR emissions. To further characterize the properties of the magnetic field, we calculate magnetic shear $\tilde{S}$, weighted shear angle $\tilde{\theta}$, and magnetic inclination angle $\varphi$. Here $\tilde{S}$ is defined as the product of field strength and shear angle $\tilde{S} = B \cdot \theta$ (Wang et al. 1994, 2006; Jing et al. 2008), where $B = |B|$, $\theta = \cos^{-1}(B \cdot B_p)/(B B_p)$, and the subscript $p$ represents the potential field. The weighted shear angle of a region of interest with $n$ pixels is then $\tilde{\theta} = \sum_i \tilde{S}_i/\sum_i B_i$, where $i = 1, 2, \ldots, n$. The inclination angle $\varphi$ relative to the horizontal plane is $\varphi = \tan^{-1}(|B_y|/(B_x^2 + B_y^2)^{1/2})$. From the results shown in Figures 2(b)–(d), it can be clearly seen that $\langle \tilde{S} \rangle$, $\tilde{\theta}$, and $\langle \varphi \rangle$ exhibit an abrupt change in the field strength, inclination angle, and azimuthal angle by about 400 G radian, 7°, and −10°, respectively, within the same transition time as $\langle B_h \rangle$ upon the flare occurrence. Please note that in order to demonstrate that the rapid changes are very significant compared to variations seen in the long-term evolution, we plot the $3\sigma_{\text{pre}}$ (3$\sigma_{\text{pos}}$) as error bars in Figure 2, where $\sigma_{\text{pre}}$ ($\sigma_{\text{pos}}$) is derived from the linear fit of the temporal evolution of each quantity in the preflare (postflare) state. Corroborating our previous studies (Wang & Liu 2010 and references therein), the above rapid developments evidenced by the unambiguous HMI observation strongly suggest a more horizontal and sheared state of the photospheric magnetic field at region R after the flare. We note that although the increase of $\tilde{S}$ and $\tilde{\theta}$ seems contrary to the relaxation of nonpotentiality as required to energize eruptions, it has been demonstrated using field extrapolations that the increase is localized and both $\tilde{S}$ and $\tilde{\theta}$ decrease above a certain height (Jing et al. 2008; Sun et al. 2011; Liu et al. 2011a). The magnetic free energy in the three-dimensional volume is reduced after the flare.

On the spatial relationship between the field change and flare emissions, the region R lies between the earliest conjugate HXR footpoint sources at ∼01:49 UT (Figure 1(c)) and the ends of the double J-shaped flare ribbons (Figure 1(d)). Intriguingly, AIA 94 Å images show two extra footpoint-like flare brightenings, FP3 and FP4, at the two far ends of the flaring PIL (Figure 1(e)). Co-spatial HXR emissions at FP3 and FP4 were observed few minutes later (Figure 1(f)), and the motion of HXR footpoints as well as the evolution of chromospheric ribbons generally

proceed in such a manner as to reduce the magnetic shear, along
the PIL (illustrated by the arrows in Figure 1(f)) as reported in
eruptive sigmoid (e.g., Ji et al. 2008). These lead us to a picture as
we schematically illustrate in Figure 3, where the flare could
be triggered by the tether-cutting reconnection (Moore et al.
1995, 2001) between the two sets of sigmoidal loops FP3–FP2
and FP4–FP1 as clearly discernible in EUV images, which
results in the J-shaped flare ribbons (also see Schrijver et al.
2011). The reconnected large-scale fields FP3–FP4 could erupt
outward to become the halo CME associated with this flare,
and the newly formed smaller loops FP1–FP2 lying close to
the surface could then account for the enhanced $B_h$ at region R.
Such a reconnection of two current-carrying loops would also
effectively lead the current path to move downward closer to
the surface, which can explain the increase of $\tilde{S}$ and $\tilde{\mathcal{S}}$ (Melrose
1997). Alternatively, increase of the magnetic nonpotentiality
at and near the surface could result from the newly emerging,
shaped magnetic flux (Jing et al. 2008), which could occur
after the relaxation of fields above the surface due to the flare
energy release. It is worth mentioning that the region R at
the PIL is between flare ribbons/kernels at opposite polarities,
hence the observed field changes cannot be attributed to flare
emissions (Patterson & Zirin 1981; Qiu & Gary 2003). Detailed
investigation of the flare HXR emission in further relation to the
coronal field dynamics is out of the scope of the current study
and will be presented in a subsequent publication.

4. SUMMARY AND DISCUSSION

We have used the unprecedented SDO/HMI vector field ob-
servations to analyze the changes of the photospheric magnetic
field associated with the first X-class flare in solar cycle 24, with
the aid of images of flare emissions in multiple wavelengths. The
main results are as follows.

1. A compact region R along the flaring PIL shows a rapid
and permanent enhancement of $\langle B_h \rangle$ by 400 G ($\sim$30% of
the preflare magnitude) within about 30 minutes, which has
a close temporal relationship with the flare HXR emission.
Meanwhile, the nonpotentiality represented by magnetic
shear also exhibits a pronounced increase near the surface.

2. The initial HXR sources FP1 and FP2 as well as the double
J-shaped flare ribbons are at the two ends of region R lying
at the central of this sigmoidal active region. Two additional
flare footpoints FP3 and FP4 are clearly seen in the hot 94 Å
channel, located at the far ends of the sigmoid. We suggest
that the tether-cutting reconnection (Moore et al. 2001)
between the loops FP3–FP2 and FP4–FP1 produces the short and low-lying loops FP1–FP2, which could explain the enhanced $B_h$ as well as $\tilde{S}$ and $\tilde{\mathcal{S}}$ at region R (Melrose
1997). The detected enhancement of nonpotentiality on the
surface could also be due to the newly emerging, sheared
fields (Jing et al. 2008).

In summary, the HMI observations presented in this study
constitute the first solid evidence of flare-induced changes of the
photospheric magnetic field, which strongly supports our pre-
vious results using ground-based vector magnetograms subject
to seeing variation (Wang & Liu 2010 and references therein).
The unambiguously observed enhancement of horizontal field
on the surface strongly suggests that the photospheric magnetic
field could respond to the coronal field restructuring by tilting
toward the surface (i.e., toward a more horizontal state) near
the PIL, and that this development may be due to the tether-
cutting reconnection producing the flare. This view is also well
in line with the recent theoretical development (Hudson et al.
2008; Fisher et al. 2011), where the back reaction on the solar
surface resulting from the coronal field evolution as required by
the energy release is quantitatively assessed. Further systematic
studies of flare-related magnetic field change, especially when
aided by extrapolation models, are promising to provide further
insight into the relationship between the surface field change
and coronal magnetic reconnection (e.g., Sun et al. 2011; Liu
et al. 2011a).

SDO is a mission for NASA’s Living With a Star program.
RHESSI is a NASA Small Explorer. Hinode is a Japanese
mission developed and launched by ISAS/JAXA, collaborating
with NAOJ as a domestic partner, and NASA (USA) and STFC
