Recently emerged variants of SARS-CoV-2 contain in their surface spike glycoproteins multiple substitutions associated with increased transmission and resistance to neutralising antibodies. We have examined the structure and receptor binding properties of spike proteins from the B.1.1.7 (Alpha) and B.1.351 (Beta) variants to better understand the evolution of the virus in humans. Spikes of both variants have the same mutation, N501Y, in the receptor-binding domains. This substitution confers tighter ACE2 binding, dependent on the common earlier substitution, D614G. Each variant spike has acquired other key changes in structure that likely impact virus pathogenesis. The spike from the Alpha variant is more stable against disruption upon binding ACE2 receptor than all other spikes studied. This feature is linked to the acquisition of a more basic substitution at the S1-S2 furin site (also observed for the variants of concern Delta, Kappa, and Omicron) which allows for near-complete cleavage. In the Beta variant spike, the presence of a new substitution, K417N (also observed in the Omicron variant), in combination with the D614G, stabilises a more open spike trimer, a conformation required for receptor binding. Our observations suggest ways these viruses have evolved to achieve greater transmissibility in humans.
The SARS-CoV-2 spike glycoprotein is the major surface antigen of the virus. Its function is to bind the host receptor ACE2 and mediate the subsequent membrane fusion required for cell entry. The virus has evolved in the human host during the pandemic and we and others have demonstrated that the predominant D614G substitution, located in a monomer-monomer interface of the spike trimer, increases its propensity to adopt the open conformation that is competent to bind receptor. The D614G substitution has been shown to decrease shedding of S1 from spike on virions, consistent with increased stability of the pre-fusion conformation. Recently emerging variants of SARS-CoV-2 have acquired other substitutions in the spike including a number located at the monomer-monomer interfaces, at the receptor-binding site, and near the furin-cleavage site (Supplementary Fig. 1). Here we have examined the structures and receptor-binding properties of spikes of the B.1.1.7 variant first described in Kent, United Kingdom (now termed Alpha) and the B.1.351 variant first described in South Africa (now termed Beta). We used pre-fusion-stabilised spikes which have been established as a tool to study the receptor-binding properties in the absence of the conformational change associated with fusion. This enabled us to directly compare the pre-fusion spikes of the new variants with those of the original strain (first identified in Wuhan) and the D614G-only variant described in previous studies, findings that agree with reports that used non-stabilised spikes.

Two recent studies showed increased RBD ectrolability and enhanced receptor binding by the Alpha and Beta spikes. Our findings confirm and extend these observations, providing insights into their structures with bound receptor; and revealing several characteristics that these variant spikes evolved to optimise their interaction with the host, which could explain their increased infectivity.

**Results and discussion**

First, examination of the 2D class averages (Supplementary Fig. 2) of ACE2-bound Alpha spike with its furin site intact reveals that all spikes in this dataset are present as trimers (Fig. 1a, Supplementary Table 1). This is the first cleaved SARS-CoV-2 spike protein in complex with ACE2 we have observed to remain fully trimeric upon receptor binding. A substantial proportion of all other spike/ACE2 complexes are dissociated into monomers. For human ACE2 if residue 614 is a glycine but not if it is an aspartic acid. The engineered G614D spike (Y501, D614) shows the same binding affinity as Wuhan (N501, D614) (Fig. 2a, b; Supplementary Fig. 3b). Incubation of this uncleaved spike with the furin inhibitor, decanoyl-Arg-Val-Lys-Arg-chloromethylketone, which resulted in an almost completely uncleaved protein (Supplementary Fig. 3b). Incubation of this uncleaved spike with ACE2 resulted in more than 50% of particles being monomeric S1-S2/ACE2 (Fig. 1a, Supplementary Fig. 2). This conformation, like that of the Wuhan strain S1-S2/ACE2 complex, is incompatible with the trimeric structure (Fig. 1b). This might be the result of some local effect not immediately evident, such as the recently reported allosteric effects of ACE2 binding on the local dynamics of the S1-S2 linker, or a consequence of the (disordered) S2 moiety carried along with the dissociated S1:ACE2 from the uncleaved protein, since preponderance of monomer S/ACE2 species in other SARS-CoV-2 variants, such as Wuhan (Fig. 1a) and Beta (Supplementary Fig. 4), correlates with the lower levels of cleavage of these spikes (Supplementary Fig. 3). In addition our structures of unbound, uncleaved Alpha spike (Supplementary Figs. 5 and 6) suggest the trimeric state of the receptor-bound form of the Alpha variant spike might be further stabilised by the substitutions D1118H and A570D on the intermonomer interfaces (Supplementary Fig. 5), as also recently suggested by Yang et al.

Second, in line with a recent study by Cai et al., we found enhanced binding of ACE2 to Alpha and Beta variant spikes when compared to Wuhan by surface biolayer interferometry. The data (Fig. 2a, b; Supplementary Fig. 7) show a sixfold increase in binding strength for Alpha spike, and a twofold increase for Beta spike (compared to Wuhan) arising from the shared substitution N501Y in the RBD. The substitution of the asparagine at position 501 in Wuhan for a tyrosine residue in both Alpha & Beta variants (Fig. 2c) leads to an increase in hydrophobic interactions between the aromatic ring of Y501(RBD) and the aromatic ring of Tyr-41(ACE2) and the aliphatic moiety of Lys-353(ACE2) in addition to a charged hydrogen bond between the phenolic hydroxyl of Tyr-501(RBD) and Lys-353(ACE2) (Fig. 2d). The smaller increase in affinity for ACE2 of the Beta spike versus Alpha spike, is consistent with the finding that, whereas Alpha has retained the same salt bridge as Wuhan between Lys-417(RBD) and Asp-30(AECE2), the RBD of Beta has acquired the additional substitution of an asparagine at residue 417 which cannot make the equivalent salt bridge (Fig. 2e).

To understand the evolution of receptor binding, we also expressed Alpha spike with an aspartic acid, rather than glycine residue, at position 614. The substitution D614G (relative to Wuhan) occurred earlier in the evolution of SARS-CoV-2, became the predominant global form of the virus and continues to be present in the Alpha and Beta variant forms of the virus. The engineered G614D Alpha spike (Y501, D614) shows the same binding affinity as Wuhan (N501, D614) (Fig. 2a, b; Supplementary Fig. 7). Similarly, we also show that the Y453F substitution in the RBD of mink spike, a structure of which we also report here (Supplementary Figures 4–6), only increases affinity for human ACE2 if residue 614 is a glycine but not if it is an aspartic acid (Supplementary Fig. 7).

Third, the most striking feature of the structure of Beta spike revealed by cryoEM is that all the trimers adopt an open conformation. This is in contrast to our earlier study, under the same conditions, that showed 83% of Wuhan spike particles were in the closed form (Fig. 3a). Again, solution equilibria cannot be extracted from these data but we interpret this near-complete switch in states as indicative of the open form of the Beta variant being more stable than the open form of Wuhan. Two recent studies also report Beta spike showing a higher proportion of open conformation relative to earlier viruses. Inspection of the sequence of the Beta spike and comparison of its structure with that of the closed form of Wuhan spike and the open and closed forms of G614 spikes, suggests that the opening of Beta spike could be driven by the substitution K417N on the background of G614 (both also observed in the Omicron variant spike). In Wuhan,
Lysine at residue 417 on the RBD not only makes an aliphatic packing interaction with Tyr-369 of the neighbouring subunit, it also forms a salt bridge/hydrogen bond network with Glu-406 and Arg-403 of the RBD and with Ser-373 of the neighbouring RBD that stabilises the closed conformation. In contrast, the substitution of an asparagine at position 417 in Beta removes an intramolecular salt bridge and would generate a steric clash with Tyr-369 of the neighbouring RBD leading to destabilisation of the closed form (Fig. 3b). In the same way that G614 is a prerequisite for realising tighter receptor binding by the substitution N501Y described above, it may also enable spike protein from the Beta virus to achieve an open conformation as a result of the K417N substitution.

We have shown that the almost fully cleaved Alpha spike is more stable as a receptor-bound trimer than the Wuhan or Beta spikes which are subject to less efficient cleavage. We cannot explain why near-complete cleavage produces more stable spike/ACE2 complexes but similar increases in stability have been observed following cleavage of the influenza haemagglutinin precursor29,30 and we suggest that such enhanced stability increases the likelihood of productive membrane fusion events. The recent variants of concern B.1.617 (Kappa) and B.1.617.2 (Delta)31–33 contain the substitution P681R, which also results in full cleavage (Supplementary Fig. 3c). Our data suggest that this substitution P681R in Kappa and Delta spikes, as well as P681H in Omicron spike, will also increase stability of the receptor-bound form of these spikes, accounting at least in part for their increased transmissibility. Our binding data on the variants and engineered constructs show that the D614G substitution is a prerequisite for the tighter receptor binding of changes in RBD,
Fig. 2 Variant spike binding to receptor ACE2. a $K_d$ of variant spikes binding to ACE2 measured using biolayer interferometry and calculated from $k_{on}/k_{off}$ analysis (see Supplementary Fig. 7 for details). b Plots of fractional saturation binding measurements with data for the Alpha variant shown in red, Alpha variant with G614D substitution in pink, and Wuhan (D614) spike in blue. Wuhan (*the data for which shown here are adapted from our previous work47) and Alpha D614 spike show almost identical affinity towards ACE2. Similar results were obtained for G614 vs D614 mink (Y453F) spike (Supplementary Figs. 4 and 7). c cryoEM density of the complex of Beta variant S1 with ACE2, with ACE2 coloured in green, RBD in rosby brown, RBD subdomain in plum, with the remaining S1 disseminated density in cream. d, e Detail of changes in the binding interfaces present in variants (left column) compared to the Wuhan strain (right column). d The N501Y substitution present in both the Beta and Alpha variants allows formation of a new hydrogen bond or a salt bridge. e The K417N substitution present in the Beta variant eliminates a salt bridge between the RBD and ACE2. Source data are provided as a Source Data file.

Methods

Construct design. The SARS-CoV-2 spike constructs used in this study were derived by Genscript from the spike ectodomain (residues 1-1208) constructs of the Wuhan variant cloned into pcDNA3.1(−) described before54. The variant spikes were stabilised in the pre-fusion conformation (K986P and V987P)29 with the furin-cleavage site ([PH]RRAR) either intact (2P constructs) or mutated to the uncleavable sequence PSRAS (FUR2P constructs). The following variant spikes were made (SA20, Alpha19 and mink34) (all mutations listed with reference to the NCBI sequence YP_009724390.1): 2P Alpha (Δ69-70, Δ144, N501Y, A570D, D614G, P681H, T716A, S982A, D1118H, and R682S, R685S, K986P, V987P), FUR2P Alpha (Δ69-70, Δ144, N501Y, A570D, D614G, T716A, S982A, D1118H, and R682S, R685S, K986P, V987P), FUR2P D614 Alpha (Δ69-70, Δ144, N501Y, A570D, T716A, S982A, D1118H, and R682S, R685S, K986P, V987P), 2P G614D Alpha (Δ69-70, Δ144, N501Y, A570D, T716A, S982A, D1118H, and R682S, R685S, K986P, V987P), FUR2P Alpha (Δ69-70, Δ144, N501Y, A570D, D614G, T716A, S982A, D1118H, and R682S, R685S, K986P, V987P), 2P Alpha (Δ69-70, Δ144, N501Y, A570D, D614G, T716A, S982A, D1118H, and R682S, R685S, K986P, V987P), 2P Alpha (Δ69-70, Δ144, N501Y, A570D, D614G, T716A, S982A, D1118H, and R682S, R685S, K986P, V987P). The Wuhan spikes and ACE2 ectodomain construct (residues 19-615) used in this study were exactly as described before5,8.

Protein expression and purification. All the variant spikes were expressed in suspension-cultured Expi293F cells (Gibco) cells and purified as described before for the D614G spike12. In brief, Expi293F cells were cultured at 37°C, shaking at 125 rpm, in humidified 8% CO2 atmosphere in FreeStyle 293 Expression Medium and transfected with 1 mg of spike DNA per litre of culture at cell density of $3 \times 10^6$/mL. For expression in presence of a furin inhibitor, decanoyl-Arg-Val-Lys-chloromethylketone (also known as “furin inhibitor I”) was prepared as a 23.5 mg/mL stock solution in DMSO and added to the cells at final concentration of 100 µM half an hour prior to transfection. Next day after transfection, the cells were harvested and the cell pellets were stored at -80°C. For the purified protein, the concentration was determined by absorbance at 280 nm using an extinction coefficient of 134,000 M⁻¹ cm⁻¹. After concentration, the protein was flash-frozen in liquid nitrogen.

The supernatant was harvested on the fourth day post transfection and the spike purified using cobalt NTA beads (TAKARA). The protein was then eluted with 200 mM imidazole, concentrated, and either flash-frozen or gel filtered (Supplementary Fig. 2e) at room temperature into a buffer containing 150 mM

steric clash and interfering with the network of electrostatic interactions present at the trimer interface in the closed form of the Wuhan protein. Strongly receptor-binding-competent form.

The Beta variant adopts only open conformations with either one (64%) or two (36%) of the RBDs in the erect, NATURE COMMUNICATIONS | (2022) 13:1178 | https://doi.org/10.1038/s41467-022-28768-w | www.nature.com/naturecommunications

K417N substitution present in the Beta variant likely destabilises the closed form of the protein by introducing a steric clash and interfering with the network of electrostatic interactions present at the trimer interface in the closed form of the Wuhan protein. Strongly charged R417 in the fully-closed Pangolin-CoV spike seems to stabilise the same network of RBD-RBD interactions.

NaCl, TRIS pH 8 on a Superdex 200 Increase 10/300 GL column (GE Life Sciences). Wuhan spikes and ACE2 were made exactly as described before5,8.

Biolayer interferometry. Measurements of spike variants affinity towards human ACE2 ectodomain were performed at 25°C on an Octet Red 96 instrument (Fortebio) with shaking at 1000 rpm in 150 mM NaCl, 20 mM TRIS pH 8. First, variant spikes at 40–80 µg/ml were immobilised for 40–60 min on NiNTA sensors pre-equilibrated in buffer. Then, the ACE2 binding was measured using 2–5 min association and 10–20 min dissociation phases. At least three independent measurements were made for each spike.

The data were analysed using kinetic and equilibrium methods. For equilibrium analysis, the data were first normalised by dividing by the maximum observable response in order to give fractional saturation as a function of ACE2 concentration.

The $K_v$ was then determined from analysis of the variation of fractional saturation with ACE2 concentration. For kinetic analysis, plots of the observed rate ($k_{on}$) were derived from association phases using a single exponential function and $k_{off}$ were obtained from plots of $k_{obs}$ vs ACE2 concentration as the slope and intercept respectively.

CryoEM data processing. Collected movies were motion corrected using MotionCor250 implemented in RELION and contrast transfer functions estimated using CTFFind4. Particles were picked using cryoSPARC using manually trained models. Particles were extracted 2x downsampled in RELION before two rounds 2D classification in cryoSPARC. Classes that showed clear secondary structure were retained and an initial model generated also using cryoSPARC. Particles from the selected classes were 3D classified in RELION. The selection process for the different data collections are shown in Supplementary Figs. 3, 4, 6.

CryoEM sample preparation. Samples were frozen on R212 400 mesh Quantifoil grids glow-discharged for 30 s at 25 mA. A sample at 0.5–0.8 mg/ml final concentration of the spike was supplemented with 0.1% (final concentration) octyl glucoside, 4 µL of it applied on a grid, blotted for 5 s to 6 s with filter paper pre-equilibrated at 4°C in 100% humidity, and plunge frozen in liquid ethane using Vitrobot Mark III. In order to obtain ACE2-spike complexes the proteins were mixed at 2:1 molar ratio of ACE2 to spike trimer and incubated at room temperature for 20–40 min prior to grid freezing.

CryoEM data collection. Data were collected using EPU software (Thermo Scientific) on Titan Krios microscopes operating at 300 kV either with a Falcon 3 camera (Thermo Scientific) operating in electron-counting mode (60 s exposures, total dose of 35 e−/Å², fractionated into 30 frames, 1.09 Å² calibrated pixel size) or K2 camera (Gatan) with GIF Quantum LS energy filter (Gatan) with a slit width of 20 eV operating in the zero-loss mode (9.4 s exposures, 49 e−/Å² total dose, fractionated into 32 frames, 1.08 Å² calibrated pixel size). The following eight datasets were collected (Supplementary Table 1): FUR2P Beta (Falcon 3), ACE2 + FUR2P Beta (K2), FUR2P Alpha (Falcon 3), ACE2 + FUR2P D614 Alpha (K2), ACE2 + 2P Alpha furin-uninhibited (Falcon 3), ACE2 + 2P Alpha furin-inhibited (Falcon 3), FUR2P mink (K2), ACE2 + FUR2P D614 mink (K2). All micrographs were collected with defocus range between 1.5 and 3 µm.

Model building, refinement, and validation. High-resolution models of the monomeric S-ACE2 complexes were based on the previously determined model for the non-uniform map refinement of the monomeric Wuhan spike in complex with ACE2 (PDB 7A91). The low-resolution model of the monomeric Alpha S-ACE2 complex was built from the non-uniform-refined, high resolution model of the same protein from this study combined with the monomeric Wuhan S-ACE2 (PDB 7A92).
D614G spike (PDB IDs 7BNM, 7BNN, 7BNO)\(^{12}\). The model of the three-ACE2-bound trimer of the 2P Alpha spike was based on the three-ACE2-bound Wuhan spike we determined before (PDB ID 7A9Y)\(^{8}\), in which the RBD (spike residues 333–527) and ACE2 were replaced by those from the monomeric, non-uniformly-refined Alpha S-ACE2 determined in this study. All structures were manually adjusted in COOT\(^{40}\), refined with PHENIX Real Space Refine and validated in PHENIX\(^{13}\). Measurements were performed with CCP4mg\(^{32}\) and Chimera\(^{46}\).
