Abstract

We report the results of mean field and the Monte Carlo study of the dynamic magnetization-reversal transition in the Ising model, brought about by the application of an external field pulse applied in opposition to the existing order before the application of the pulse. The transition occurs at a temperature $T_\text{c}$ below the static critical temperature $T_\text{c}$ without any external field. The transition occurs when the system, perturbed by the external field pulse competing with the existing order, jumps from one minimum of free energy to the other after the withdrawal of the pulse. The parameters controlling the transition are the strength $h_p$ and the duration $\Delta t$ of the pulse. In the mean field case, approximate analytical expression is obtained for the phase boundary which agrees well with that obtained numerically in the small $\Delta t$ and large $T$ limit. The order parameter of the transition has been identified and is observed to vary continuously near the transition. The order parameter exponent $\beta$ was estimated both for the mean field ($\beta = 1$) and the Monte Carlo ($\beta = 0.90 \pm 0.02$ in two dimension) cases. The transition shows a "critical slowing-down" type behaviour near the phase boundary with diverging relaxation time. The divergence was found to be logarithmic in the mean field.
case and exponential in the Monte Carlo case. The finite size scaling technique was employed to estimate the correlation length exponent $\nu = 1.5 \pm 0.3$ in two dimension) in the Monte Carlo case.

1 Introduction

The dynamic response of pure Ising systems to time dependent magnetic fields is being studied intensively these days (see e.g. [1, 2] and references therein). In particular, the response of Ising systems to pulsed fields have recently been investigated [3, 4]. The pulse can be either ”positive” or ”negative”. At temperatures $T$ below the critical temperature $T_c$ of the corresponding static case (without any external field), majority of the spins orient themselves to a particular direction giving rise to the prevalent order. If the external field pulse is applied along the direction of the existing order, it is called a positive pulse and if the pulse is applied opposite to the existing order, it is called a negative pulse. The effect of positive pulse has been studied by Acharyya et al [3], whereas the occurrence of a magnetization-reversal transition as a result of the application of the negative pulse has been reported in an earlier work [4]. We report here the results of detailed investigation of this dynamic magnetization-reversal transition for pure Ising models under a pulsed field.

In the absence of any symmetry breaking field, for temperatures below the critical temperature of the corresponding static case ($T < T_c$), there are two equivalent free energy minima with average magnetizations $+m_0$ and $-m_0$. If in the ordered state the equilibrium magnetization is $+m_0$ (say) and the pulse is applied in the direction opposite to the existing order, then temporarily during the pulse period the free energy minimum with magnetization $-m_0$ will be brought down compared to that with $+m_0$. If this asymmetry is made permanent, then any nonzero field (strength), which is responsible for the asymmetry, would eventually induce a transition from $+m_0$ to $-m_0$. Instead, if the field is applied in the form of a pulse, the asymmetry in the free energy wells is removed after a finite period of time. In that case, the point of interest lies in the combination of the pulse height or strength ($h_p$) and its width or duration ($\Delta t$) that can give rise to the transition from $+m_0$ to $-m_0$. We call this a magnetization-reversal transition. A crucial point about the transition is that it is not necessary that the system attains
its final equilibrium magnetization \(-m_0\) during the presence of the pulse; the combination of \(h_p\) and \(\Delta t\) should be such that the final equilibrium state is attained at any subsequent time, even long time after the pulse is withdrawn. The phase boundary, giving the minimal combination of \(h_p\) and \(\Delta t\) necessary for the transition, depends on the temperature. As \(T \to T_c\), the magnetization reversal transition occurs at lower values of \(h_p\) and/or \(\Delta t\) and the transition disappears at \(T \geq T_c\).

In this paper we have given both the mean field (MF) and the Monte Carlo (MC) results for the transition. The MC studies have been carried out for a two dimensional \((d = 2)\) lattice of Ising spins. The phase boundaries in the \(h_p - \Delta t\) plane (each for a fixed \(T\)) are obtained for both the MF and the MC cases. Approximate analytical expressions are also obtained and compared to these phase boundaries. The order parameter \((O)\) for the dynamic transition has been identified and at a fixed \(T\) its variation with the driving parameters \(h_p\) and \(\Delta t\) has been studied. The observed continuous variation of \(O\) indicates the nature of the transition to be comparable to the second order type static transitions. The critical exponents for the order parameter variations near the phase boundary has been obtained for both the MF and MC cases. We also employed the finite size scaling method (see e.g [4]) to estimate the correlation length exponent \(\nu\) for the transition in the MC studies. We observe significant ”critical slowing down” near the phase boundary and the behaviour of the relaxation time \(\tau\) has been studied in both the cases. In the MF case, we have obtained an approximate analytical expression for \(\tau\) indicating clearly a different kind of divergence of \(\tau\) as compared to that in the static case.

2 Model

We have taken Ising Model for both the numerical simulation and mean field study. The Hamiltonian of nearest neighbour Ising system without any disorder is

\[
H = -J \sum_{<ij>} S_i S_j - h(t) \sum_i S_i, \quad (1)
\]

where \(S_i = \pm 1\) represents the Ising spins at lattice site \(i\) and \(J\) denotes the nearest neighbour interaction strength. The time dependent external
magnetic field $h(t)$ is applied in the form of a pulse of duration $\Delta t$

\[ h(t) = -h_p, \quad \text{for} \quad t_0 < t < t_0 + \Delta t \]
\[ = 0, \quad \text{otherwise.} \tag{2} \]

t_0 is taken to be much larger than the relaxation time of the unperturbed system so that the system is guaranteed to reach a state of equilibrium before the pulse is applied. The average magnetization $m$ is given by $\langle S_i \rangle$, where the angular brackets represent thermal average. By the time $t = t_0$, the system has reached its equilibrium state with the magnetization $m(t) = \pm m_0$. This is the state before the application of the pulse, which is applied at time $t = t_0$ to compete with the initial magnetization. We then want to look at the dynamics of the system under a pulsed field starting with the initial condition $m(t_0) = +m_0$ (say). Depending on the strength ($h_p$) or the duration ($\Delta t$) of the pulse, the system has two choices after the pulse is withdrawn: it can either go back to the original ordered state ($m(t = \infty) = +m_0$), or it can switch to the other equivalent equilibrium ordered state ($m(t = \infty) = -m_0$). Fig. 1 shows schematically these behaviours. The result, at any finite temperature below $T_c$, naturally depends on the strength and the duration of the pulse. Specifically, we observe that the result depends on $m_w \equiv m(t_0 + \Delta t)$, the average magnetization at the time of withdrawal of the field. The sign of $m_w$, which in turn depends on the combination of $h_p$ and $\Delta t$, governs the transition. $|m_w|$ was found out to be the appropriate candidate for the order parameter: if $m_w$ becomes negative, on an average one observes a magnetization-reversal transition; however if $m_w$ is positive, the system is most likely to return back to its original equilibrium state. In fact, it is guaranteed to be so in the mean field case. However in MC simulations, there exists occasional fluctuations due to which the system may finally arrive at the $+m_0$ state starting with negative $m_w$ and vice versa. We have identified the $h_p - \Delta t$ phase boundary at a particular temperature which gives the optimum combination of the driving parameters ($h_p$ and $\Delta t$) that can force the system to a final state with magnetization $-m_0$, starting from an initial state with magnetization $+m_0$ or vice versa. We define the relaxation time $\tau$ as the time taken by the system to reach its final equilibrium state from the time of withdrawal of the field (at $t = t_0 + \Delta t$). The relaxation time increases as the value of $|m_w|$ approaches zero or equivalently as one
approaches the phase boundary from either side. In Fig. 2 the typical MC results (on a square lattice) show how the transition can be brought about by either increasing $h_p$ (see Fig. 2(a)) or $\Delta t$ (see Fig. 2(b)). One can also note from these figures how the relaxation time $\tau$ increases as one approaches the phase boundary.

3 Mean Field Study

The mean field equation of motion for the average magnetization $m(t)$ of the system is

$$\frac{dm}{dt} = -m + \tanh \left( \frac{m + h(t)}{T} \right),$$

where $h(t)$ is given by (2). Here we have assumed $Jn = 1$, where $n$ is the lattice coordination number. With this choice, the critical temperature in the static limit ($T_c$) becomes unity. All the mean field calculations are performed, therefore, at a temperature $T < 1$. The equation was solved numerically to obtain the phase boundaries, shown in Fig. 3. A point on a particular phase boundary gives the optimal combination of $h_p$ and $\Delta t$ that can induce the transition from a state with magnetization $+m_0$ to $-m_0$, where $m_0 = \tanh(m_0/T)$. The axes side of the boundaries correspond to the return to original equilibrium state, whereas one gets a magnetization-reversal transition for combinations of $h_p$ and $\Delta t$ beyond the phase boundary. Because of the absence of any fluctuations in the mean field equation (3), there exists a finite coercive field for $T < T_c$ and therefore one cannot bring about the transition just by increasing $\Delta t$ if $h_p$ does not exceed the coercive field value. Hence the phase boundary becomes parallel to $\Delta t$ axis for large values of $\Delta t$.

For large $T$, the mean field phase boundary can be estimated approximately by solving the linearized mean field equation

$$\frac{dm}{dt} = -\epsilon m + \frac{h(t)}{T} ; \quad \epsilon = \frac{1 - T}{T},$$

where $h(t)$ is given by (2). The solution of (4) for $t > t_0$ can be written as

$$m(t) = \left( m_0 - \frac{h_p}{\epsilon T} \right) \exp[\epsilon(t - t_0)] + \frac{h_p}{\epsilon T}. $$

5
It may be noted from the solution \(\text{(5)}\) that \(t\) has to be close to \(t_0\) in order to keep the value of \(m(t)\) small, so that the linearization in \(\text{(4)}\) is valid. The magnetization-reversal transition occurs if \(m(t_0 + \Delta t) \leq 0\). The phase boundary can therefore be obtained from \(\text{(5)}\) by putting \(m_w = m(t_0 + \Delta t) = 0\). The resulting equation for the phase boundary is then

\[
h^c_p = \frac{m_0 \epsilon T}{1 - \exp(-\epsilon \Delta t)}. \tag{6}\]

In Fig. 3, this analytic result for the phase boundary has been compared with those obtained by solving numerically equation \(\text{(3)}\). As one can clearly see from the figure that the agreement is good in the small \(\Delta t\) region of the phase boundaries for large values of \(T\).

As mentioned before, the magnetization \(m_w\) at the time of withdrawal of the pulse, seems to be the crucial quantity governing the transition. The sign of \(m_w\) solely decides the final equilibrium state of the system out of the two equilibrium choices. Therefore we define the mean field order parameter \((\mathcal{O})\) as following

\[
\mathcal{O} = m_w \theta(m_w), \tag{7}\]

where the step function \(\theta\) is defined as

\[
\theta(x) = \begin{cases} 
1, & \text{for } x > 0 \\
0, & \text{otherwise}. 
\end{cases}
\]

The nature of variation of \(\mathcal{O}\) with \(| h_p - h^c_p |\) at different values of \(\Delta t\) and \(T\) is shown in Fig. 4. Here \(h^c_p = h^c_p(\Delta t, T)\) is obtained from the phase boundary. We fitted the order parameter variations to the power law form

\[
\mathcal{O} \sim | h_p - h^c_p |^\beta \tag{8}
\]

and found the value for the exponent \(\beta \simeq 1\) by fitting the numerical results for different values of \(\Delta t\) and \(T\).

The relaxation time \((\tau)\) grows as the phase boundary is approached from either side and shows a divergence on the boundary. We measure the relaxation time by measuring the time required by \(m(t)\) to reach the final
equilibrium value \( \pm m_0 \), with an accuracy of \( O(10^{-4}) \), from the time of withdrawal of the pulse. According to (3) and (8), for a fixed \( \Delta t \), \( m_w \sim | h_p - h_c^p | \). Therefore \( \tau \) is also expected to diverge as \( m_w \) vanishes. Fig. 5 shows that this is indeed the case and the growth of the relaxation time was found to be logarithmic in nature. That the relaxation time will diverge logarithmically at the phase boundary at any temperature below the static critical temperature \( (T < 1) \) can be shown analytically. Let us follow the mean field dynamics of the system after the withdrawal of the field. The system starts with a magnetization \( m_w \) and evolves according to (3) with \( h(t) = 0 \) to reach the final state of equilibrium characterized by magnetization \( \pm m_0 \). Keeping the value of \( m/T \) small we expand \( \tanh \) of (3) up to the cubic term:

\[
\frac{dm}{dt} = \epsilon m + \alpha m^3, \quad (9)
\]

where \( \alpha = -1/(3T^3) \). Thus we can write

\[
\int_0^\tau dt = \int_{m_0}^{m_w} \frac{dm}{\epsilon m + \alpha m^3},
\]
or,

\[
\tau = -\frac{\ln m_w}{\epsilon} + \frac{\ln(\epsilon + \alpha m_w^2)}{2\epsilon} + C(T), \quad (10)
\]

where \( C(T) \) is a constant depending on temperature only. Now, if the combination of \( h_p \) and \( \Delta t \) is such that one starts with very small value of \( m_w \), then one gets

\[
\tau \sim -\frac{1}{\epsilon} \ln | m_w |. \quad (11)
\]

It can be easily verified that even if the \( O(m^5) \) term in the expansion of (3) is kept, the final result (11) does not get modified in the \( m_w \to 0 \) limit. The above form for the variation of \( \tau \) fits accurately the numerical results: at \( T = 0.6 \), \( 1/\epsilon = 1.5 \), and this matches exactly with the numerical result as shown in Fig. 5. The above analysis also makes it very clear that the logarithmic divergence of \( m_w \) implies a similar divergence with \( | h_p - h_c^p | \) for a fixed \( \Delta t \). It may be mentioned here that for the dynamic magnetization-reversal transition, the above divergence in \( \tau \) occurs at any \( T < T_c \). The same equation (11) also gives the well known \( | T - T_c |^{-1} \) divergence of \( \tau \) for the static transition at \( T = T_c = 1 \). It may also be noted from (11) that
the logarithmic dependence of $\tau$ on $| h_p - h_p^c |$, through its dependence on $m_w$, for this dynamic transition at $h_p^c(\Delta t, T < T_c)$ is qualitatively different from the divergence of $\tau (\sim | T - T_c |^{-1})$ for the static transition in the same model (equation 3) at $T = T_c$.

4 Monte Carlo Study

For the MC simulation we have taken Ising spins on a square lattice of size $L \times L$, with $L = 200$ for typical studies. Each spin of the lattice were updated sequentially using the Glauber single spin flip dynamics [6]. Phase boundaries at different temperatures below the static critical temperature ($T_c \simeq 2.27$) shows qualitatively similar nature to that in the mean field case. However, unlike the mean field phase diagrams, the presence of fluctuations causes the MC phase diagrams to touch the abscissa asymptotically. When the contributions of fluctuations become important at higher values of $T$ and small values of $h_p$, the above MF theory fails. If $h_p \to 0$ (as in the large $\Delta t$ region of the phase boundary), one can use the picture of nucleation of a single domain. The classical nucleation theory of Becker and Döring (see e.g. [7]) suggests that the nucleation rate $I \sim \exp[-F(l_c)/T]$ is given by the optimality condition $l_c = [\sigma(d-1)/2d]/h_p$ of free energy $F(l) = 2h_pl^d + \sigma l^{d-1}$ for the formation of a droplet or domain of linear size $l$ under field $h_p$. Here $\sigma$ is proportional to the surface tension for the formation of a droplet. Equating the growth rate given by Becker and Döring nucleation rate $I$ with the inverse pulse width, one gets $\Delta t \simeq \exp(1/h_p^{d-1})$, suggesting

$$h_p^c \ln \Delta t = \text{constant},$$

along the phase boundary in two dimensions. It agrees fairly well with the MC estimated phase diagram in the low $h_p$ (i.e. large $\Delta t$) limit [4, 5]. For large values of $h_p$, the critical droplet size $l_c \sim 1/h_p$ being much smaller than the system size $L$, many droplets grow simultaneously and the transition occurs due to coalescence of the droplets and not by the above-mentioned process of growth of a single droplet. The equation (12), therefore, fails to fit the phase boundary for large values of $h_p$ and hence for small values of $\Delta t$.

Similar to the MF case [7], we define the order parameter in the same way: $\mathcal{O} = m_w \theta(m_w)$, where $\theta$ is the step function and $m_w$ is the average
magnetization at the time of withdrawal of the pulse. Fig. 6 shows the variation of this order parameter with $|h_p - h_p^c|$ for different values of $\Delta t$ and $T$. Typical number of initial seed values taken to generate the configurations over which each data point is averaged is 500. The variation of $O$ was again fitted to the power law form (8) with the order parameter exponent $\beta$ and we find $\beta \sim 1$ by fitting the MC results for four different values of $\Delta t$ and four different values of $T$.

Here also we estimate the relaxation time $\tau$ by measuring the time (MC steps) required for $m(t)$ to reach the final equilibrium value $\pm m_0$ from the time of withdrawal of the pulse with a predefined accuracy $O(10^{-2})$. Again $\tau$ was found to diverge as the phase boundary (at any fixed $T$) is approached from either side. Fig. 7 shows that the divergence of $\tau$ occurs at the point where $m_w$ vanishes at the phase boundary. It is not possible to average the relaxation time for different realizations of the dynamics for a particular $m_w$, as different realizations produce different values of $m_w$. Therefore a small range of $m_w$ was taken, instead of a particular value, to take an average of $\tau$. A typical value of the range of $m_w$ over which averaging has been done is 0.01. It was observed that $\tau$ depends on the driving parameters $h_p$, $\Delta t$ and temperature $T$ only implicitly through the quantity $m_w$. The divergence of $\tau$ was found to be very sharp and it fitted with an exponential function ($\tau \sim \exp |m_w|$) unlike the mean-field case where $\tau$ was seen to behave logarithmically with $|m_w|$.

We fitted above the MC results for $L = 200$ and extracted the value of the exponent $\beta$, assuming the finite size effects to be negligible. As $h_p \rightarrow h_p^c$, for finite $L$ one should consider the effective $h_p^c$ to be a function of $L$. Therefore one should consider an additional scaling function of $L/\xi$ in (8), where $\xi \sim |h_p - h_p^c|^{-\nu}$ is the correlation length with exponent $\nu$. Assuming that $\xi \sim L$ for such MC cases, we can write the appropriately modified form of (8) as

$$O \sim L^{-\beta/\nu} f((h_p - h_p^c)L^{1/\nu}).$$

(13)

We have fitted the data for different $L$ to the scaling form (13). The data for $L= 50, 100, 200$ and 400 for a particular value of $\Delta t$ ( =5) and two different values of $T$ were scaled to obtain the fitting values of the exponents as shown in Fig. 8. Typical number of averages over different initial seeds taken for the MC data was 2500 for $L = 50$ and 50 for $L = 400$. With such a scaling fit procedure, $h_p^c$ could be obtained with an accuracy of 0.001. This gives
\[ \beta = 0.90 \pm 0.02 \text{ and } \nu = 1.5 \pm 0.3. \] It was observed that the quality of fitting does not change appreciably for variation of the fitting parameters within the error limits specified above.

## 5 Discussions

The recently reported \cite{4} dynamic magnetization-reversal transition in pure Ising model under a pulsed (negative) magnetic field has been studied extensively in this paper employing the mean field approximation as well as the Monte Carlo technique in two dimension. Accurate estimates have been made for the phase boundary \( h_p^c(\Delta t, T) \), both in MF and MC cases. Approximate analytic estimates of the phase boundary have been made in both the cases and compared with the numerical results obtained. The order parameter for this dynamic transition has been identified and it is given by the average magnetization at the time of withdrawal of the pulse. In the mean field approximation the order parameter was found to vary linearly with \( |h_p - h_p^c| \), indicating the order parameter exponent \( \beta = 1 \); while in the MC case \( \beta \) was found to be around 0.9 for \( d = 2 \). The application of the finite size scaling method gives the value of the critical exponent \( \nu \) for the correlation length to be nearly 1.5 for \( d = 2 \). Besides the length scale, a time scale was also found to diverge both in case of mean field and the Monte Carlo studies. In the mean field case, the relaxation time \( \tau \) was found to diverge logarithmically with \( m_w \), or equivalently with \( |h_p - h_p^c| \), as the phase boundary is approached. This has been demonstrated to be true analytically also. However, the divergence of \( \tau \) was found to be stronger in the Monte Carlo case, where \( \tau \) diverges exponentially with \( m_w \) or with \( |h_p - h_p^c|^{\beta} \) (with \( \beta \approx 0.90 \) in \( d = 2 \)) as the phase boundary is approached. The finite size scaling results suggested that the correlation length diverges as \( |h_p - h_p^c|^{\nu} \) at the phase boundary with \( \nu \approx 1.5 \) in \( d=2 \). The existence of the divergence of both the length scale and the time scale indicates the thermodynamic nature of this intriguing dynamic magnetization-reversal transition in the Ising model.
