We use dynamical mean field theory to find an exact solution for inelastic light scattering in strongly correlated materials such as those near a quantum-critical metal-insulator transition. We evaluate the results for \(q = 0\) (Raman) scattering and find that resonant effects can be quite large, and yield a triple resonance, a significant enhancement of nonresonant scattering peaks, a joint resonance of both peaks when the incident photon frequency is on the order of \(U\), and the appearance of an isosbestic point in all symmetry channels for an intermediate range of incident photon frequencies.

PACS numbers: 78.30.-j, 71.10.-w, 71.27.+a, 71.30.+h, 78.20.Bh

Inelastic light scattering is a powerful tool to unravel the nature of elementary excitations in a wide variety of materials [1], ranging from Kondo insulators [2, 3], to high temperature superconductors [4, 5], to colossal magnetoresistance materials [6]. The experimental efforts have grown tremendously with the availability of third generation light source facilities and improvements in CCD detectors. These efforts have been brought to bear on strongly correlated materials to examine the elementary excitations of insulators and metals and how they evolve as the correlations are made to change via doping, for example.

One of the most studied areas is how the scattering cross section resonates with the incoming light frequency. It is widely believed that by tuning the incident photon frequency, features of the non-resonant spectra can be magnified by orders of magnitude; that is, the resonance serves as a bootstrap to raise the intensity of the non-resonant signal. However, a full, consistent theory is lacking [7, 8]. Non-resonant scattering is derivable from a two-particle correlation function which can be treated by a variety of techniques, yet the resonant and mixed contributions involve higher particle correlations and are difficult to treat theoretically due to multiple-particle vertex renormalizations. Most of the approaches to light scattering in insulators examine the Loudon-Fleury model [9] which is appropriate for off-resonant conditions for the scattering of light off of spin excitations, for example. In the strong-coupling regime, a perturbative approach has been used to illustrate a number of important features of electronic resonant scattering processes [8, 10]. The nonresonant case has also been examined, and an exact solution for correlated systems (in large spatial dimensions) is available for both the Falicov-Kimball [11] and Hubbard [12] models. Here we concentrate on an exact solution of the full problem for the Falicov-Kimball model including all non-resonant, resonant and mixed scattering channels.

For an electronic system with nearest-neighbor hopping, the interaction with a weak external transverse electromagnetic field \(A\) is described by [8]

\[ H_{\text{int}} = \frac{e}{\hbar c} \mathbf{j} \cdot \mathbf{A} + \frac{e^2}{2\hbar^2 c^2} \sum_{\alpha\beta} A_\alpha \gamma_{\alpha\beta} A_\beta, \]

where

\[ j_\alpha = \sum_k v_\alpha(k)c_\sigma^\dagger(k + q/2)c_\sigma(k - q/2), \]

is the current operator, \(v_\alpha(k) = \partial \varepsilon(k)/\partial k_\alpha\) is the Fermi velocity, and

\[ \gamma_{\alpha\beta} = \sum_k \frac{\partial^2 \varepsilon(k)}{\partial k_\alpha \partial k_\beta} c_\sigma^\dagger(k + q/2)c_\sigma(k - q/2) \]

is the stress tensor operator. The inelastic light-scattering cross section becomes (\(\Omega = \omega_i - \omega_f\), \(q = k_f - k_i\) is the transferred photon frequency and momentum, respectively):

\[ R(\Omega) = R_N(\Omega) + R_M(\Omega) + R_H(\Omega), \]

where the nonresonant contribution is

\[ R_N(\Omega) = \frac{2\pi g_i^2(k_i) g_f^2(k_f)}{\mathcal{Z}} \times \sum_{ij} \exp(-\beta \varepsilon_i) \hat{\gamma}_{ij} \hat{\gamma}_{ji} \delta(\varepsilon_f - \varepsilon_i - \Omega), \]
the mixed contribution is

\[ R_M(\Omega) = 2\pi g^2(\mathbf{k}_i)g^2(\mathbf{k}_f) \sum_{ijf} \exp(-\beta \varepsilon_i) \]

\[ \times \left[ \tilde{\gamma}_{ijf} \left( \frac{j_{ij}^{(f)}}{j_{ij}^{(i)}} \left( \frac{\varepsilon_{f} - \varepsilon_{i} - \omega_{i} + i0^+}{\varepsilon_{f} - \varepsilon_{i} - \omega_{i} + i0^+} + \frac{\varepsilon_{i} - \varepsilon_{f} + \omega_{f} + i0^+}{\varepsilon_{i} - \varepsilon_{f} + \omega_{f} + i0^+} \right) \right) \right. \]

\[ + \left( \frac{j_{ij}^{(i)}}{j_{ij}^{(f)}} \left( \frac{\varepsilon_{i} - \varepsilon_{f} - \omega_{i} - i0^+}{\varepsilon_{i} - \varepsilon_{f} - \omega_{i} - i0^+} + \frac{\varepsilon_{f} - \varepsilon_{i} + \omega_{f} + i0^+}{\varepsilon_{f} - \varepsilon_{i} + \omega_{f} + i0^+} \right) \right) \tilde{\gamma}_{ijf} \]

\[ \times \delta(\varepsilon_{f} - \varepsilon_{i} - \Omega), \quad (6) \]

and the resonant contribution is

\[ R_R(\Omega) = 2\pi g^2(\mathbf{k}_i)g^2(\mathbf{k}_f) \sum_{ijf} \exp(-\beta \varepsilon_i) \]

\[ \times \left( \frac{j_{ij}^{(i)}}{j_{ij}^{(f)}} \left( \frac{\varepsilon_{f} - \varepsilon_{i} - \omega_{i} - i0^+}{\varepsilon_{f} - \varepsilon_{i} - \omega_{i} - i0^+} + \frac{\varepsilon_{i} - \varepsilon_{f} + \omega_{f} + i0^+}{\varepsilon_{i} - \varepsilon_{f} + \omega_{f} + i0^+} \right) \right) \]

\[ \times \left( \frac{j_{ij}^{(f)}}{j_{ij}^{(i)}} \left( \frac{\varepsilon_{i} - \varepsilon_{f} + \omega_{i} + i0^+}{\varepsilon_{i} - \varepsilon_{f} + \omega_{i} + i0^+} + \frac{\varepsilon_{f} - \varepsilon_{i} - \omega_{f} - i0^+}{\varepsilon_{f} - \varepsilon_{i} - \omega_{f} - i0^+} \right) \right) \]

\[ \times \delta(\varepsilon_{f} - \varepsilon_{i} - \Omega). \quad (7) \]

Here \( \omega_{ij} \) and \( \mathbf{k}_{ij} \) denote the energy and momentum of the initial (final) states of the photons, \( \varepsilon_{ij} \) are the eigenvalues corresponding to the eigenstates that describe the “electronic matter”, and \( g(\mathbf{k}) = (\hbar c^2/V\omega_k)^{1/2} \) is the “scattering strength” with \( \omega_k = \epsilon(\mathbf{k}) \). We have introduced the following symbols

\[ \tilde{\gamma} = \sum_{\alpha, \beta} e_{\alpha}^i \gamma_{\alpha \beta} e_{\beta}^f, \quad j_{ij}^{(i)}(f) = \sum_{\alpha} e_{\alpha}^i j_{\alpha}, \quad (8) \]

with the notation \( O_{ij} = \langle i | O | f \rangle \) for the matrix elements of an operator \( O \), \( Z \) the partition function, and \( e_{\alpha}^i \) are the incident and scattered light polarization vectors, respectively. We concentrate on the light scattering response function \( \chi(\Omega) \), which is related to the cross section, but with a Bose statistical factor removed:

\[ R(\Omega) = \frac{2\pi g^2(\mathbf{k}_i)g^2(\mathbf{k}_f)}{1 - \exp(-\beta \Omega)} \chi(\Omega). \quad (9) \]

Inelastic light scattering examines charge excitations of different symmetries by employing polarizers on both the incident and scattered light. The \( A_{1g} \) symmetry has the full symmetry of the lattice and is primarily measured by taking the initial and final polarizations to be \( e^i = e^f = (1, 1, 1, \ldots) \). The \( B_{1g} \) symmetry involves crossed polarizers: \( e^i = (1, 1, 1, \ldots) \) and \( e^f = (-1, 1, -1, 1, \ldots) \); while the \( B_{2g} \) symmetry is rotated by 45 degrees, with \( e^i = (1, 0, 1, 0, \ldots) \) and \( e^f = (0, 1, 0, 1, \ldots) \). While a symmetry analysis can be employed for all momentum transfers \( \mathbf{q} \), for Raman \( (\mathbf{q} = 0) \) scattering, it is easy to show that for a system with only nearest neighbor hopping and in the limit of large dimensions, the \( A_{1g} \) sector has contributions from nonresonant, mixed, and resonant scattering, the \( B_{1g} \) sector has contributions from nonresonant and resonant scattering only, and the \( B_{2g} \) sector is purely resonant [11]. The symmetry analysis would be substantially different for lower dimensions but is not currently tractable. A full analysis for all \( \mathbf{q} \) will be presented elsewhere and therefore for the remainder of the paper we focus on Raman scattering \( (\mathbf{q} = 0) \) only.

Normally the matrix elements defined in Eq. (8) cannot be easily determined for a many-body system in the thermodynamic limit. Instead, the light scattering cross section expressions must be evaluated by first considering the relevant multi-time correlation functions on the imaginary time axis, then Fourier transforming to a Matsubara frequency representation, and finally making an analytic continuation from the imaginary to the real frequency axis. In the case of nonresonant scattering, the expressions to be analytically continued depend on only one frequency; for mixed scattering they depend on two frequencies, and for resonant scattering, they depend on three. The analytic continuation procedure for the mixed and resonant Raman scattering is complicated, because it requires a multistep procedure, where first the transferred frequency is continued to the real axis, then the individual initial and final frequencies are continued to the real axis. In addition to the analytic continuation, we also must evaluate the dressed multi-time correlation functions. There are renormalizations associated with two-particle “ladder-like” summations for a number of the relevant diagrams, but the symmetry of the velocity operator, and of the relevant multi-particle vertex functions (which are local in the large-dimensional limit) imply that there are no parquet-like summations, nor are there any three- or four-particle vertex renormalizations [13]. Since the two-particle vertex function for the Falicov-Kimball model is already known [14], the full Raman scattering problem can be solved via a straightforward but tedious procedure. The final formulas are cumbersome and will be presented elsewhere.

The Falicov-Kimball model Hamiltonian satisfies [15]

\[ H = -\frac{t^*}{2\sqrt{d}} \sum_{\langle ij \rangle} (c_i^\dagger c_j + c_j^\dagger c_i) + U \sum_i c_i^\dagger c_i w_i \quad (10) \]

where \( c_i^\dagger \) (\( c_i \)) create (annihilate) a conduction electron at site \( i \), \( w_i \) is a classical variable (representing the localized electron number at site \( i \)) that equals 0 or 1, \( t^* \) is a renormalized hopping matrix that is nonzero between nearest neighbors on a hypercubic lattice in \( d \)-dimensions (and we take the limit \( d \rightarrow \infty \) [16]), and \( U \) is the local screened Coulomb interaction between conduction and localized electrons. This model can be solved exactly by using dynamical mean field theory, as described by Brandt and Mielisch [17] and summarized in review articles [18].

We concentrate on the case with \( U = 2 \) here, which is just on the insulating side of the metal-insulator transition at half filling \( \langle n_e \rangle = \langle n_i \rangle = 1/2 \). This was the regime where the nonresonant response showed a num-
ber of interesting properties for both Raman [11] and inelastic x-ray scattering [19]. The Stokes Raman response function is plotted in Fig. 1 at $T = 0.5$ for 9 different incident photon frequencies $\omega_i$ ranging from 0.5 to 4.5 in steps of 0.5. Since the transferred energy can be no larger than the incident photon energy, all scattering curves run from zero up to $\omega_i$. The first thing to note in Fig. 1 is the large nearly vertical line that occurs as $\Omega \rightarrow \omega_i$. This is the triple resonance [10], which yields a strong enhancement to the Raman scattering when the energy of the scattered photon approaches zero. In the Loudon-Fleury regime [9], where the incident photon energy is much larger than the electronic excitation energies, we see that the full response is essentially that of the nonresonant response [11] plus the triple-resonance peak. As the incident photon energy is reduced, the behavior becomes much more complex. Generically we can identify a number of low-energy and higher-energy resonant enhancements to the scattering.

![FIG. 1: Raman response function for different channels. We take $U = 2$, $T = 0.5$, and choose $\omega_i = 0.5 - 4.5$ in steps of 0.5 (the different line thicknesses correspond to different $\omega_i$'s).](image)

One interesting feature of the response function, seen in experiments on correlated materials [2, 3], and seen in theoretical calculations of the nonresonant response [11, 12], is that at low energy there is an isosbestic point, where the $B_{1g}$ response function is essentially independent of temperature at a particular frequency $\Omega \approx U/2$. Below that frequency the response decreases as $T$ is lowered, and above it increases. The isosbestic behavior must survive in the Loudon-Fleury regime, because the isosbestic point is at low energy, and the low-energy response is negligible in the resonant and mixed contributions. But what happens when $\omega_i \approx U$? Here we expect interesting effects to occur, because the incident photon energy is the right size to cause transitions from the lower to upper Hubbard bands of the correlated insulator. Indeed, we find interesting results in this regime (Fig. 2). At low temperature ($T < 0.7$), a symmetry-dependent isosbestic point appears at a transferred frequency of 0.7–0.9 and is seen in all channels at low enough $T$, even the $A_{1g}$ and $B_{2g}$ channels, which have no isosbestic point in the nonresonant regime. Hence the inclusion of resonant and mixed terms provides theoretical support for the generic presence of a low-temperature isosbestic point in correlated systems.

![FIG. 2: Raman response function for $U = 2$ and $\Omega = 2$ for different channels at $T = 1$, $T = 0.5$, $T = 0.2$, and $T = 0.05$. The temperature decreases as the lines are made thicker.](image)

Finally, we present results of what the resonant profile of the scattering looks like by fixing the transferred frequency and varying the incident photon energy. We expect that there will be a resonant peak in the response, and indeed this is so, although in some cases the triple resonance overwhelms the presence of the peak. Note that in high-temperature superconductors, in addition to the expected resonance that occurs when the incident photon frequency is close to the transferred frequency, another resonance occurs, where the low-energy peak is strongly enhanced when $\omega_i \approx U$ [4, 5]. We show this regime in Figs. 3 ($\Omega = 2.0$) and 4 ($\Omega = 0.5$). In Fig. 3 we see a moderately broad peak centered at $\omega_i 10–20\%$ higher than $U$. The enhancement of the charge-transfer peak in this regime can easily be an order of magnitude over the nonresonant response. In Fig. 4, we see a similar resonant feature when the incident photon frequency is slightly larger than $\Omega = 0.5$ (arising from the triple-resonance effect), but a second less prominent series of broad peaks occurs when $\omega_i \approx U$ indicating that the low-energy and charge transfer peaks are resonating to-
gether when $\omega_i \approx U$. Hence the behavior observed in the high-temperature superconductors [4, 5] is likely to be seen in many other correlated insulators.

In conclusion, we have shown a number of interesting resonant features in theoretical calculations of electronic Raman scattering. These features include the triple resonance, the resonant enhancement of nonresonant peaks, the appearance of isosbestic points, and the joint resonance of low-energy and charge-transfer peaks when $\omega_i \approx U$. It will be interesting to see whether these predictions can be seen in future experiments on correlated systems.
