Abstract. During the months of June and July 2013, over the Euro–Mediterranean area, the ADRIMED (Aerosol Direct Radiative Impact on the regional climate in the MEDiterranean region) project was dedicated to characterize the ozone and aerosol concentrations in the troposphere. It is first shown that this period was not highly polluted compared to previous summers in this region, with a moderate ozone production, no significant vegetation fire events and several precipitation periods scavenging the aerosol. The period is modeled with the WRF (Weather Research and Forecasting) and CHIMERE models, and their ability to quantify the observed pollution transport events is presented. The CHIMERE model simulating all kinds of sources (anthropogenic, biogenic, mineral dust, vegetation fires); the aerosol speciation, not available with the measurements, is presented: during the whole period, the aerosol was mainly constituted by mineral dust, sea salt and sulfates close to the surface and mainly by mineral dust in the troposphere. Compared to the AERONET (Aerosol Robotic Network) size distribution, it is shown that the model underestimates the coarse mode near mineral dust sources and overestimates the fine mode in the Mediterranean area, highlighting the need to improve the model representation of the aerosol size distribution both during emissions, long-range transport and deposition.

1 Introduction

The Euro–Mediterranean region is surrounded by many urbanized and agricultural lands in the north and arid regions in the south. This leads to numerous different pollution sources with a majority of anthropogenic and biogenic sources in the north and mineral dust in the south. In addition, mainly during summer, vegetation fires are often observed. As previously studied by Moulin et al. (1998), Middleton and Goudie (2001), Kubilay et al. (2003) and Israelevich et al. (2012), among others, the summer period is characterized by a south to north flow from Africa, transporting mineral dust in the free troposphere, and a north to south flow transporting trace gases and particles of anthropogenic origin in the boundary layer, as summarized in Fig. 1.

In order to study the atmospheric composition over this region, the experimental part of the Aerosol Direct Radiative Impact on the regional climate in the MEDiterranean
region (ADRIMED) project (Mallet, 2014) was conducted during June and July 2013. ADRIMED is part of the international program ChArMEx (Chemistry–Aerosol Mediterranean Experiment; Dulac et al., 2013), aiming at assessing the present and future state of atmospheric chemistry in the Mediterranean area and its impact on regional climate, air quality, and marine ecosystems. This project complements several previous studies dedicated to the analysis of ozone and aerosols over the Mediterranean area.

Gerasopoulos et al. (2005) showed that ozone is controlled by production over the continent and may reach up to 60 ppb in the eastern Mediterranean marine boundary layer. Kalabokas et al. (2008) showed that the high concentrations observed are mainly driven by the anticyclonic meteorological conditions occurring during the summer. During the MINOS campaign (Mediterranean Intensive Oxidant Study; Lelieveld et al., 2002) over the same region, Roelofs et al. (2003) reported ozone concentrations in altitude of about 50 ppb, with peaks reaching 120 ppb. Lidar observations of ozone undertaken during the ESCOMPTE campaign (Expérience sur site pour contraindre les modèles de pollution atmosphérique et de transport d’émissions; Cros et al., 2004), in summer in the western part of the Mediterranean showed that highly concentrated plumes may be formed over a given country and transported for several hundreds of kilometers, before reaching ground levels (Colette et al., 2006).

Aerosols are also highly variable in space, time and composition. Their composition can be quantified by the relative contribution of various chemical species such as organic matter, sulfates, nitrates, ammonium, mineral dust and sea salt (Millan et al., 2005; Monks et al., 2009). Many experimental research programs were recently conducted to characterize the aerosol properties using surface measurements (Querol et al., 2009), airborne measurements (Dulac and Chazette, 2003), optical depths measured by sunphotometers (Kub persisted, lidar measurements including EARLINET (European Aerosol Research Lidar Network to Establish an Aerosol Climatology; Papayannis et al., 2008; Pappalardo et al., 2014) or satellite data (Barnaba and Gobbi, 2004). Remotely sensed surface measurements are also used to better quantify the dust optical properties and direct radiative forcing as in Bergamo et al. (2008), Basart et al. (2009), Mallet et al. (2013), and di Sarra et al. (2008). The integrated project EUCAARI (dedicated to the Aerosol Climate Air Quality Interactions; Kulmala et al., 2011) was conducted to better characterize the aerosol life cycle and composition in Europe, integrating many types of aerosol studies, from the nano to the global scales, with a large scientific community.

These measurements have been accompanied by significant development in regional and global chemistry transport models (CTMs). For example, ozone was simulated using the CHIMERE regional CTM during the ESCOMPTE campaign (Menut et al., 2005) and the summertime ozone maximum was analyzed using the TOMCAT global CTM (Richards et al., 2013). Aerosol observations in the Mediterranean area often show large contributions from mineral dust, so that numerous studies were devoted to this species (Pérez et al., 2011; Nabat et al., 2012; Menut et al., 2013b; de la Paz et al., 2013). Their impact on climate via their radiative effect was recently analyzed with the models COSMO (Vogel et al., 2009), RegCM (Santese et al., 2010), SKYRON (Spyrou et al., 2013) and ALADIN-Climate (Nabat et al., 2014). Other important and still not well represented natural sources are now also included in CTMs. For example, sea salt was modeled in Jiménez-Guerrero et al. (2011) and vegetation fires in Turquety et al. (2014).

All these studies show that the ozone and aerosol are difficult to model in this region. Due to many different sources and their large variability, models have to include an accurate representation of all possible sources at the same time and of numerous chemical species. But, the more there is sources and chemistry, the more there are uncertainties in the modeling. To quantify the ability to retrieve the ozone and aerosol content and variability in the Euro–Mediterranean region, the WRF (Weather Research and Forecasting) and CHIMERE models are used to simulate the atmospheric composition from 1 June to 15 July 2013. A large domain, encompassing northern Africa and Europe, is designed to take into account all possible ozone precursors and aerosol sources and allows for contributions from long-range transport. The model results are compared to the available measurements and scores are presented. Having in mind the models’ performances, the ozone and aerosol composition is further analyzed. For ozone, the variability is quantified both at the surface and in altitude. For aerosol, the model provides additional information such as composition and size distribution. Section 2 presents the experimental framework of the ADRIMED campaign and the whole set of data (surface, soundings, aircraft measurements, satellite) used in this study. Section 4 presents the modeling system and the settings. Section 5 ana-
lyzes the meteorological situation using E-OBS data and the WRF model. Sections 6, 7 and 8 present ozone concentration, aerosol optical depth (AOD) and aerosol concentrations results, respectively. Sections 9 and 10 present aerosol speciation and size distribution. Conclusions and perspectives are presented in Sect. 11.

2 Observations

In order to characterize the meteorological situation and the atmospheric composition, and to estimate the realism of the models, many observations are used in this study. An overview of the pollution over the area is done with the MODIS (Moderate Resolution Imaging Spectroradiometer) satellite AOD measurements. With the surface measurements of the E-OBS database, the temperature and the precipitation are characterized. Using the EEA (European Environmental Agency) network, the surface ozone and particulate matter concentrations are studied. The optical depth is quantified using the AERONET (Aerosol Robotic Network) network. Temperature and ozone variabilities are estimated in the troposphere thanks to the aircraft observations of the ADRIMED project. The location of the measurement sites used in this study is summarized in Table 1. Stations are sorted as a function of distance from the sea: the “coastal” stations are inland but less than 10 km from the coast and the “continental” stations are more than 10 km from the coast.

2.1 E-OBS meteorological measurements

Comparisons with the daily average 2 m temperature and precipitation amount taken from the European Climate Gridded data set (E-OBS; Haylock et al., 2008) are undertaken. This data set contains data collected from several thousands of meteorological stations throughout Europe and the Mediter-
2.2 EEA chemical measurements

For regulatory pollutants, many measurements are routinely performed and well organized in quality-checked databases. The EEA (Guerreiro et al., 2013) is responsible for the AirBase database used in this study. It contains surface concentration measurements and information submitted by the participating countries throughout Europe (http://www.eea.europa.eu/). For this study, we focused on ozone and PM$_{10}$. In order to calculate scores and to study time series, a subset of data is used, including eight “coastal background” and nine “continental background” stations. Their location is displayed in Fig. 2 and details about their coordinates are provided in Fig. 1. They were chosen to be representative of various locations around the western Mediterranean Sea: Spain, France and Italy, including the Baleares, Corsica and Lampedusa islands. These stations are all “background” stations to ensure a correct representativity between the measured and the modeled values.

2.3 AERONET measurements

The AERONET photometer measurements (Holben et al., 2001) are used to characterize the observed AOD and the volume aerosol size distribution (ASD). The AOD data are recorded by numerous stations deployed around the world and hourly values are available. Several quality levels are proposed on the AERONET database (http://aeronet.gsfc.nasa.gov/). In this study, the level 2.0 is used for AOD and the level 1.5 for ASD (Dubovik and King, 2000). The stations used in this study are listed in Table 1 and their location is displayed in Fig. 2.

2.4 ADRIMED measurements

The experimental part of the ADRIMED experiments includes surface measurements (at the supersites of Cape Corsica and Lampedusa), remote sensing and airborne measurements, as presented in Mallet (2014). The airborne measurements are analyzed for ozone concentrations. These measurements were performed onboard the ATR-42 aircraft (operated by the SAFIRE CNRS, CNES and Météo-France joint laboratory). Nine flights were conducted during the studied period. The flight numbers, date and decimal hour, and corresponding day of flight are reported in Table 2. Trajectories are very different from one flight to another and are represented in Fig. 3 on a map and in Table 4 to see the vertical extension of the flights.

3 Air quality during the ADRIMED period

The first step is to evaluate if the ADRIMED period was highly polluted or not, compared to previous summers in this...
Table 3. Number of days in June, July and August when (i) surface daily mean concentrations of PM$_{10}$ exceed the threshold value of 30 µg m$^{-3}$, and (ii) surface daily maximum concentrations of ozone exceeds 120 µg m$^{-3}$. Data are extracted from the model cell corresponding to the location.

4 Modeling system

The modeling system is composed of several models: the WRF regional meteorological model, the CHIMERE CTM and additional individual models dedicated to emission flux estimations. All these models are integrated in a modeling platform usable both in analysis and forecast modes. The simulation was performed from 1 June to 15 July 2013.

4.1 WRF meteorological model

The meteorological variables are modeled with the non-hydrostatic WRF regional model in its version 3.5.1 (Skamarock et al., 2007). The global meteorological analyses from NCEP/GFS (Kalnay et al., 1996) are provided on a regular 1.125° × 1.125° grid. They are hourly read by WRF using nudging techniques for the main atmospheric variables (pressure, temperature, humidity, wind). In order to preserve both large-scale circulations and small-scale gradients and variability, the “spectral nudging” was chosen. This nudging was evaluated in regional models, as presented in Von Storch et al. (2000). In this study, the spectral nudging was selected to be applied for all wavelengths greater than ≈ 2000 km (wave numbers less than 3 in latitude and longitude, for wind, temperature and humidity and only above 850 hPa). This configuration allows the regional model to create its own structures within the boundary layer but makes sure it follows the large-scale meteorological fields.

In this study, the model is used with a constant horizontal resolution of 60 km × 60 km and 28 vertical levels from the surface to 50 hPa, as displayed in Fig. 5. The Single Moment-5 class microphysics scheme is used, allowing for mixed-phase processes and supercooled water (Hong et al., 2004). The radiation scheme is the RRTMG scheme with the MCICA method of random cloud overlap (Mlawer et al., 1997). The surface layer scheme is based on Monin–Obukhov with the Carlsn–Boland viscous sublayer scheme. The surface physics is calculated using the Noah Land Surface Model scheme with four soil temperature and mois-
turing layers (Chen and Dudhia, 2001). The planetary boundary layer physics is processed using the Yonsei University scheme (Hong et al., 2006) and the cumulus parameterization uses the ensemble scheme of Grell and Devenyi (2002).

4.2 CHIMERE chemistry-transport model

CHIMERE is a CTM allowing the simulation of concentration fields of gaseous and aerosol species at a regional scale. It is an offline model, driven by precalculated WRF meteorological fields. In this study, the version fully described in Menut et al. (2013a) is used. The simulations are performed over the same horizontal domain as the one defined for WRF, with a constant resolution of 60 km × 60 km. The 28 vertical levels of the WRF simulations are projected onto 20 levels from the surface up to 300 hPa.

The chemical evolution of gaseous species is calculated using the MELCHIOR2 scheme and that of aerosols using the scheme developed by Bessagnet et al. (2004). This module takes into account sulfate, nitrate, ammonium, primary organic matter (POM), elemental carbon (EC), secondary organic aerosols (SOA), sea salt, dust and water. The aerosol size is represented using 10 bins, from 40 nm to 40 µm in diameter. The aerosol life cycle is completely represented with nucleation of sulfuric acid, coagulation, adsorption/desorption, wet and dry deposition and scavenging. This scavenging is represented by both coagulation with cloud droplets and precipitation. The formation of SOA is also taken into account.

The photolysis rates are explicitly calculated using the FastJX radiation module (version 7.0b; Wild et al., 2000; Bian et al., 2002). The modeled AOD is calculated by FastJX and for several wavelengths: 200, 300, 400, 600 and 1000 nm. For the comparisons with the AERONET measurements, we selected the AOD calculated at 600 nm. This calculation includes absorption by ozone (over the whole atmospheric column), Rayleigh scattering, Mie diffusion by liquid water and ice water clouds, absorption and Mie diffusion by aerosols. In this model version, the aerosol is dry. A complete analysis of the improvement obtained in the model with this online calculation is fully described in a companion paper (Mailler et al., 2015).

At the boundaries of the domain, climatologies from global model simulations are used. In this study, outputs from LMDz-INCA (Szopa et al., 2009) are used for all gaseous and aerosol species, except for mineral dust. For this species, simulations from the GOCART model are used (Ginoux et al., 2001).

The anthropogenic emissions are estimated using the same methodology as the one described in (Menut et al., 2012) but with the HTAP (hemispheric transport of air pollution) annual totals as input data. These masses were prepared by the EDGAR team, using inventories based on MICS-Asia, EPA-US/Canada and TNO databases (http://edgar.jrc.ec.europa.eu/national_reported_data/htap.php). Biogenic emissions are calculated using the MEGAN emissions scheme (Guenther et al., 2006) which provides fluxes of isoprene and monoterpenes. In addition to this version, several processes were improved and added in the framework of this study. First, the mineral dust emissions are now calculated using new soil and surface databases, (Menut et al., 2013b) and with a spatial extension of potentially emitting areas in Europe as described in Briant et al. (2014).

Emission fluxes produced by biomass burning are estimated using the new high-resolution fire model presented in Turquety et al. (2014). Taking into account these fluxes is a major improvement in the CHIMERE model. Figure 6 presents the locations of burned areas during the summer of 2013, as detected by the MODIS satellite-based instrument (MCD64 product at 500m resolution, processed as described in Turquety et al. (2014), and gridded onto the CHIMERE grid). The week number of first fire detection within each model grid cell ranges from 1 (the first week of June 2013) to 12 (the last week of September 2013). It shows that a majority of the first fire events occurred during weeks 8–12, i.e., during September. These fires are mainly located in Portugal and Russia and, to a lesser extent, Greece. For each model grid cell, the number of fire events is presented (i.e., the number of area-burned detections). For a large majority of diagnosed fires, this number is 1, showing there were not a lot of fires during the summer of 2013.

5 Modeled meteorology evaluation

The meteorological modeling was already done and evaluate with the WRF model, for the same kind of domain and resolution as in Mailler et al. (2013) and Menut et al. (2013b, c) for example. It was shown that the model is able to accurately reproduce the main meteorological variables over the Euro–
5.1 Daily maps

A comparison of 2 m temperature, \( T_{2m} \), (K) and precipitation amount, \( Pr \), (mm day\(^{-1}\)) is presented in Fig. 7. Three days are selected, 16, 20 and 24 June 2013, corresponding to examples every 4 days during the ADRIMED experiment. For each day and for the WRF results, the hourly 2 m temperature is averaged over the day and the hourly precipitation amount (mm h\(^{-1}\)) is cumulated to have millimeters per day. For the E-OBS observations, values are available over land only. For the WRF model, 2 m temperature and precipitation amount are available over the whole model domain, even if this domain is limited to a maximum latitude of 55° N.

For the 2 m temperature, we note that the observed and modeled values are close. For example, over Germany, a maximum of \( T_{2m} \) is observed during 20 June, also well modeled by WRF. For \( Pr \), the main structures and the relative amount are also well modeled. For 16 June, the E-OBS data diagnosed precipitations in the western part of United Kingdom, France and Spain. WRF is able to modeled this pattern and shows a large precipitation system over the Atlantic Ocean. This system is advected to the eastern part of Europe and the WRF model is able to reproduce this advection speed as well as the accumulated precipitation values. These comparisons show the model is able to reproduce the main synoptic-scale absolute values and variability observed during this period.

5.2 Daily time series

From the E-OBS data daily maps, time series are extracted for some sites in Europe, as listed in Fig. 1. From 1 June to 15 July, for the grid cell corresponding to the site location, daily averages of the WRF model hourly results are computed for the 2 m temperature, and values are cumulated for precipitation. These comparisons are displayed in Fig. 8 and statistical scores are presented in Table 4.

For \( T_{2m} \), the scores show that the correlation is high, ranging from 0.87 to 0.99. However, a non-negligible bias is calculated, ranging between \(-4.1\) and \(0.87\) K, showing the model mainly underestimates the E-OBS gridded values. This bias cannot be attributed to a problem of measurements versus model representativity, the E-OBS values being re-gridded with a \( 0.25° \times 0.25° \) resolution and the model having a \( 60 \text{ km} \times 60 \text{ km} \) horizontal resolution. This bias is more probably due to the boundary layer or microphysics schemes used with WRF in this study. The model is able to reproduce the main variability observed during the whole period: low temperatures observed in the first days of June, corresponding to precipitation events, then a warm period, with temperature increasing from \( \approx 290 \) to \( \approx 295 \) K in the period of 14–17 June. A second large precipitation event is observed from 18 to 25 June (except in Bastia) leading to a slight cooling. After 25 June, precipitations are observed and modeled but they are more moderate and the temperature increases from \( \approx 290 \) to \( \approx 295 \) K until the end of the studied period, 14 July 2013.

The daily precipitation amount \( Pr \) has to be analyzed differently than the temperature. For the temperature, the model has to provide a correct space and time variability and a bias as low as possible. For the precipitation, the space and time variability is the most important since for chemistry-transport modeling, when a precipitation event is diagnosed, the atmospheric column is scavenged. This is why, in place of correlation, we introduce here the hit rate score: for a threshold arbitrarily chosen as \( Pr_{T}=0.1 \text{ mm day}^{-1} \) (i.e., there is precipitation for this day and this site), the event is considered as true if \( Pr > Pr_{T} \). If this condition is reached for the observations and the model, a counter increments the \( a \) value. If the condition is reached for the observations and not the
model, a counter increments the $c$ value. The hit rate, HR, is defined as

$$HR = \frac{a}{a + c}. \quad (1)$$

The target value for the hit rate is 1, meaning that the model was able to catch all the observed events. Results are presented in Table 5. The number of events is also displayed since precipitations did not occur every day. The number of days under a precipitation event is between 1 and 19 for a total of 41 studied days. The HR ranges from 0.64 to 1, showing that the model reproduces this variable fairly well. One also notes that the mean bias is often negative, showing that the modeled precipitations are lower than what was observed.

6 Analysis of ozone concentrations

The first comparisons between measured and modeled atmospheric composition are undertaken for the analysis of ozone concentrations near the surface and in altitude. Ozone reflects the amount of photo-oxidant pollution, especially during summertime periods. Two kinds of data are used in this section: (i) the routine surface measurements of the AirBase
Figure 8. Time series of daily mean averaged 2 m temperature (K) and daily precipitation amount (mm day$^{-1}$) for several sites where chemical measurements are also available. Time series are extracted from maps of E-OBS daily data.
background stations and (ii) the airborne measurements done for ADRIMED with the ATR aircraft. The AirBase measurements are regular in time (hourly), and are used to quantify if the model is able to simulate both the background values and the peaks during high-pollution events. However, being only at the surface, these measurements are not dedicated to provide information on the model behavior in the whole troposphere. Thus, they do not allow for an interpretation on the ozone long-range transport. The ATR measurements are then complementary, providing vertical ozone profiles at a given time. However, unlike surface observations, they are very specific and do not reflect the overall situation of atmospheric pollution over the whole Mediterranean area.

### 6.1 Ozone surface concentration maps

Simulated surface ozone concentrations are displayed in Fig. 9. The three maps are selected to present values for the same days as for the meteorological variables in Fig. 7. For 16 June 2013, over the Mediterranean Sea, ozone values vary a lot, between 30 and 70 µg m$^{-3}$, with several plumes having a spatial extent of a few tens of kilometers only. The highest surface concentrations are modeled in the southeastern part of the domain, over Saudi Arabia. Surface concentrations are much higher on 20 June 2013 over Europe. This corresponds to the highest $T_{2m}$ values, enhancing the photochemical processes over anthropogenic sources such as Belgium and the Netherlands. Over Great Britain and France, values are low and this corresponds to cloudiness associated with the observed and modeled precipitations. On 24 June, ozone concentrations are low (less than 40 µg m$^{-3}$) over all of Europe. This corresponds to the advection of this precipitation event from west to east. Finally, these maps show that ozone concentrations were moderate during this ADRIMED period, except over Saudi Arabia.

### 6.2 Ozone surface concentrations time series

To better understand the daily variability observed on the maps, scores are calculated for daily maximum and daily mean averaged values. Results are presented in Table 6 (daily maximum) and Table 7 (hourly values). The corresponding time series are presented in Fig. 10 for the daily maximum values.

The scores reported in Table 6 show the ability of the model to capture extreme events. Depending on the location, the model simulates lower or higher maximum daily values compared to the measurements. But for all stations, the differences between the two is never more than 20 µg m$^{-3}$. The correlations are also very dispersed, with values ranging from 0.15 (Malaga) to 0.71 (Agen). One can expect to have better correlations over the continent than over the sea due to the formation processes of ozone. This is not always the case, showing the difficulty of the model to estimate daily peaks over this complex region.

The scores in Table 7 are complementary and present results for hourly values. In this case, the complete diurnal cycle of ozone formation is taken into account. The scores are often better than for the daily peaks, with values of up to 0.81 (Cordoba). The low-correlation results are obtained for Ajaccio and Malaga (0.40), Bastia (0.29) and Gap (0.36), as already diagnosed with the daily peaks. This denotes a general inability of the model to represent ozone formation and transport over these areas. For these three sites, the problem is probably related to the low model resolution, these three

sites being in mountainous or insular areas, the subgrid-scale variability of ozone remains difficult to model.

Time series of measured and modeled ozone daily maximum are displayed in Fig. 10. For the coastal stations, Ajaccio, Bastia and Zorita, the measured values show flatter time series than the modeled ones, explaining low correlations obtained in Ajaccio and Bastia. When the model overestimates the concentrations in Ajaccio, it underestimates the concentrations in Bastia, even if the locations are close and located in the island of Corsica. From a model point of view, this consists in two close (but not neighboring) grid cells. These high differences may be explained by zooming in on Corsica, as displayed in Fig. 11: ozone surface concentrations (in ppb)
are shown for 17 June 2013, 12:00 UTC, as an example. For this day, and more generally for the whole ADRIMED period, surface ozone concentrations are very variable and composed of very dense and isolated plumes. This explains the large variability of scores when comparing point by point model and surface measurements, even if the horizontal resolution is coarse.

The scores are better for continental stations as Champforgeuil and Agen. The model is able to capture the day-to-day variability, with highest values recorded for 16 and 17 June and 6–10 July. This corresponds to well-established polluted periods, but the maximum values of 140 µg m$^{-3}$ are far from high-pollution events.

### 6.3 Ozone and meteorological vertical profiles during the ATR flights

The ozone concentrations measured during the ATR flights are averaged from 1 Hz to a 5 mn time step. The number of averaged data is reported in Table 2. The simulated concentrations corresponding to the location of the measurement are interpolated in time (between the two modeled hourly outputs), vertically (between the two model vertical levels) and horizontally (using a bilinear interpolation). The comparison between the modeled and measured ozone concentrations is presented in Fig. 12. The corresponding altitude, temperature (in °C) and mean wind speed (in m s$^{-1}$) are also presented, using the abscissa axis.

Each flight lasts between 2 and 3 h. In the altitude panels, we can see that the aircraft made several iso-altitude measurements, mainly at 4000 and 6000 m. For meteorological data, the temperature is always very well simulated by the WRF model. The differences between model and measurements are very weak except, for example, for flights 30 and 31 where the temperature is slightly more underestimated by the model in altitude than close to the surface. The wind is variable and there are differences between simulated values and measurements, mostly in terms of variability, but the absolute values are correctly estimated.

Ozone is always overestimated by the model, especially in altitude. This is probably a direct effect of boundary conditions that may be too strong for this period. The boundary chemical fields are derived from a global climate model and the summer of 2013 was moderated in terms of pollution: the climatology may thus induce a positive bias in the model. These flights within the marine boundary layer are a very good opportunity to evaluate ozone concentrations over the maritime surfaces. These concentrations are usually very high in models due to a lack of deposition. This ozone deposition underestimation is rarely documented and quantified, but some previous studies showed that the dry deposition velocities used over oceans for gaseous species may be underestimated, due to a misrepresented turbulence as pointed out by Garland et al. (1980), Ganzeveld et al. (2009) and Coleman et al. (2010), for example. The differences between the model and observations are lower when the aircraft is under 1000 m a.g.l. (above ground level). Below this altitude, observed ozone concentrations values of up to 60 ppb are not always well captured by the model. This is a direct effect of
Figure 12. Comparisons between observed and modeled $O_3$ concentrations, temperature and wind speed along the flight trajectories. The top plot indicates the altitude above sea level of the flight. The abscissa represents the day of the year.
the limitation due to the horizontal resolution, the model being not able to represent local ozone plumes as presented in Fig. 9.

7 Analysis of aerosol optical depth

The AOD quantifies the extinction of radiation by aerosols along the whole atmospheric column. The comparison between model and measurements is widely used to estimate the models’ ability to reproduce aerosol plumes. However, comparisons of AOD have limitations. Being vertically integrated, there is no information on the vertical structure of the aerosol plume. In addition, AOD is estimated for a specific wavelength, not always representative of the complete size distributions of all aerosols. In this study, the CHIMERE outputs of AOD are calculated at 600 nm, due to the Fast-J algorithm used in the model.

7.1 Comparisons between MODIS and CHIMERE

As a first step, the satellite measurements are here only used to check if the main AOD patterns are well retrieved by the model. The measured AOD at 550 nm is extracted from the MODIS satellite data over the period from 6 June to 15 July 2013. Observations are interpolated on the model grid and comparisons are done for collocated data in space and time, as displayed in Fig. 13. The MODIS map includes the AOD retrieved over ocean and over land, proposed on the NASA Giovanni database. MODIS AOD products have been used for many years to study the amount and origin of aerosols in the Mediterranean troposphere. Barnaba and Gobbi (2004) used these data to split relative contributions of aerosols on AOD. They showed that for the same particle size, its origin (maritime, continental or desert dust) may induce an AOD variability of one order of magnitude. More recently, Levy et al. (2010) evaluated the MODIS AOD product over land, by comparison to AERONET sunphotometer data. They showed that there is a high correlation ($R = 0.9$) between the two AOD products, with a mean bias of 0.05.

The AOD data are time averaged over the period from 6 June to 15 July 2013 in order to have the maximum of available information on the map. Figure 13 shows that, on average for all the considered period, CHIMERE reproduces realistically the main features of the AOD over the considered region, with average values above unity for the Sahelian band and the Arabian Peninsula. However, CHIMERE misses high AOD values on the eastern side of the Caspian Sea as well as over the northern part of the Atlantic. For the first area, the underestimation of the AOD by CHIMERE may be related to missing dust emissions, while for the northern Atlantic, the high AOD values in MODIS are related to an average computed from very few data points, possibly during an event of transport of a polluted plume (e.g., biomass burning or mineral dust) from outside of the simulation domain that is not present in the global climatologies used at the boundaries. Over Europe, AOD is also underestimated where anthropogenic sources dominate.

7.2 Comparisons between AERONET and CHIMERE

Comparisons between modeled and measured AOD are also done using the AERONET data (level 2; Holben et al., 2001). Time series are presented in Fig. 14. While the station of Banizoumbou is located in a mineral dust source area, the stations of Cabo Verde and Dakar are often influenced by dust outbreaks. This explains that over the whole period, AOD values are high, ranging from 0.4 to 2. The day-to-day variability is also important and these time series show that the highest AOD values are observed during the period from 5 to 15 June. A second period with high values is between 27 and 30 June, with values of up to $AOD = 1$. The model is able to retrieve the observed day-to-day variability, even if, on average, modeled values are greater than observed ones for stations far away from the main Saharan dust sources.

Time series are also presented for the stations of Lampedusa, Forth Crete and Izana. This set of stations is represen-
tative of small islands (for Lampedusa and Izana) and remote locations (Forth Crete). The measured AOD values are always lower than 0.5. This clearly shows that, during the whole period, no intense aerosol plume was observed over the Mediterranean Sea. The comparison results are not as good as for the African stations and the model tends to overestimate the AOD over the Mediterranean area. This overestimation may be due to several factors that cannot be diagnosed only with the AOD, this quantity being an integrated budget of many possible contributions. This may be an overestimation of surface mineral dust emissions, a shift in the aerosol size distribution, or an underestimation of modeled dry deposition velocities. However, considering all these potential problems and compared to the AOD of the AERONET measurements, the modeled AOD has not an important bias and follows the observed day-to-day variability. The discrepancies are studied in the last section in terms of the aerosol size distribution.

Table 8 corresponds to statistical scores calculated over these AERONET stations. The number of observations is very variable from one station to another: if the Izana station has 516 measurements, Forth Crete has only 108. These differences are certainly due to the cloud screening algorithm applied on the raw sunphotometer data to ensure that provided AODs are only due to aerosols. The correlation is variable from one site to another with values ranging from 0.20 (Ilorin) to 0.77 (Izana) and 0.79 (Lampedusa). The RMSE is very large, of the order of magnitude of the AOD value, showing important discrepancies between model and measurements. The bias shows that the model underestimates AOD in Africa where are the mineral dust sources and tends, contrarily, to overestimate AOD for sites such as Izana and Lampedusa. This may be due to compensation errors acting differently as a function of the source types and locations: the aerosol size distribution is different between mineral dust and anthropogenic emissions; i.e., the combination of errors in the aerosol size distribution and the emitted flux may provide a correct AOD or not.

8 Analysis of PM$_{10}$ surface concentrations

The analysis of PM$_{10}$ surface concentrations is complementary to the analysis of AOD. Comparisons are here presented between surface AirBase measurements and, for the corresponding location in the model domain, PM$_{10}$ concentrations at the model’s first vertical level.

8.1 Statistical comparisons between model and observations

Table 9 presents scores for this comparison. The values are daily averaged and are expressed in micrograms per cubic meter. The number of values compared is very variable and mostly between 700 and 1000, corresponding to hourly data over the whole period. Italian stations are different and measurements are only daily, leading to a lower number of raw
Table 9. R, bias and RMSE for the daily mean averaged PM$_{10}$ ($\mu$g m$^{-3}$) surface concentrations (except for the Lampedusa measurements corresponding to total suspended particles).

| Site          | $N_{\text{obs}}$ | PM$_{10}$ daily mean | $R$ | RMSE | Bias |
|--------------|------------------|----------------------|-----|------|------|
| AirBase coastal “background” stations |                  |                      |     |      |      |
| Zorita       | 37               | 16.1                 | 15.5 | 0.59 | 8.9  | −0.5 |

| Taranto      | 39               | 19.8                 | 21.4 | 0.48 | 7.0  | 1.6  |
| Chitignano   | 40               | 10.4                 | 20.3 | 0.66 | 10.8 | 10.0 |
| AirBase continental “background” stations |                  |                      |     |      |      |
| Aranjuez     | 38               | 23.1                 | 14.3 | 0.41 | 12.8 | −8.8 |
| Logroño      | 41               | 23.2                 | 14.7 | 0.46 | 10.1 | −8.5 |
| Cordoba      | 41               | 21.2                 | 23.4 | 0.23 | 18.1 | 2.2  |
| Agen         | 41               | 14.5                 | 16.6 | −0.04| 9.7  | 2.1  |
| Champforgeuil| 41               | 15.8                 | 17.5 | 0.17 | 9.7  | 1.6  |
| Gap          | 35               | 13.0                 | 13.5 | 0.56 | 4.9  | 0.5  |
| Baceno       | 33               | 7.9                  | 12.6 | 0.38 | 8.7  | 4.8  |
| Schivenoglia | 39               | 27.5                 | 20.6 | 0.32 | 12.1 | −6.8 |
| Vercelli     | 36               | 16.3                 | 19.2 | 0.68 | 7.2  | 2.9  |

Observations. At the end, 33–41 daily averaged values are available. The observed values ranged from 7.9 (Baceno) to 32.5 µg m$^{-3}$ (Malaga). For the model, the values ranged from 12.6 (Baceno) to 30.1 µg m$^{-3}$ (Malaga). If the variability from site to site is correctly reproduced, the results showed that the model may underestimate or overestimate the concentrations, depending on the site. There is no obvious link between the location of the site and the sign of the difference: the bias may be positive or negative for sites in the same region. Depending on the station, the correlation ranges from very low (−0.02 for Cartagena and −0.04 for Agen, for example) to moderate (0.66 in Chitignano, 0.68 in Hyères, 0.68 in Vercelli). For 11 stations (on a total of 17), the bias remains lower than ±4 µg m$^{-3}$.

8.2 Surface concentration time series

The measured and modeled daily averaged surface PM$_{10}$ concentrations are presented in Fig. 15 as time series. On average, the background concentrations are well simulated for all sites. However, some discrepancies appear when some peaks are modeled but not measured, as for example at Zorita, Malaga and Agen. The lower bias on the AOD suggests that the aerosol mass is correctly but that the surface concentrations are too large. This can be, partially, a problem of exaggerated vertical diffusion, often diagnosed in deterministic Eulerian models (Vuolo et al., 2009). Another possibility is to have too important local emissions. A way to better understand this overestimation is to analyze the aerosol composition, as presented in the next section.

9 The modeled aerosol speciation

In the previous sections, the aerosol’s behavior was analyzed in terms of AOD and surface PM$_{10}$. In this section, aerosol composition is analyzed and results are presented in terms of time series of surface concentrations and vertical profiles of concentrations.

9.1 Time series

For each site, the modeled aerosol composition is presented as surface time series in Fig. 16. The concentrations are shown for the whole aerosol size distribution, i.e., for a mean mass median diameter $D_p$ from 0.04 to 40 µm. It is thus logical to have surface concentrations higher than the ones presented for the PM$_{10}$ time series. For all time series, the most important contribution comes from mineral dust, with at least 50 % of the total mass. This mineral dust part is also responsible of the large peaks observed in the PM$_{10}$ concentrations. The second most important contribution corresponds to sea salts, specifically for locations corresponding to islands or for continental sites such as Lampedusa and Cape Corsica. For “continental background” stations such as Champforgeuil and Agen, the concentrations are lower than for other stations and the relative part of sea salt becomes logically negligible. For days when there is no peak of dust and sea salt, sulfate concentrations dominate the aerosol composition. The last most important contribution is from sulfates with large concentrations modeled in Lampedusa and Malaga, among others. Finally, the relative contributions of POM and EC are very low in the total, showing in particular that this period was not influenced by large vegetation fire events.

9.2 Relative contribution of chemical species

The time series presented in the previous section showed the large temporal variability of the surface concentrations as well as the large variability of the aerosol chemical composition. In order to quantify these relative contributions site by site, the relative amount of each chemical species is estimated as a percentage of the total concentration. The calculation is done by cumulating the hourly concentrations over the whole studied period and species per species. The results are presented in Table 10. For each site, the value of the most abundant species is written in bold.

For 13 stations (out of a total of 17 stations), the most important species is mineral dust, with values ranging from 25.01 (Champforgeuil) to 64.48 % (Cordoba). In general, the sites where mineral dust dominates correspond to the western part of the Mediterranean: Zorita, Cartagena, Malaga, Aranjuez, and Cordoba (all these sites being in Spain).
The second most important contribution is sulfate: this is the most important component for the aerosols at sites Cape Corsica (28.39 %), Ajaccio (22.79 %), Bastia (28.05 %) and Schivenoglia (24.73 %). The first three sites are in Corsica and the last one in the north of Italy. For the sites in Corsica, these large amounts of sulfates are due to shipping emissions or the vicinity of the Fos-Berre industrial area in the south of France, where Schivenoglia is close to industries.

The third most important contribution is sea salt. For sites such as Lampedusa, Cartagena, and Malaga this contribution is close to the sulfate contribution values. All these sites correspond to island or coastal sites and are thus more exposed to sea salt emissions. For all continental sites, the sea salt contribution is low, between 2 (Baceno) and 12.76 % (Agen). Finally, only one site has a major contribution very different from the others: in Hyéres, the most important chemical species is POM (particulate organic matter) and this is most likely due to the proximity of the Fos-Berre area, with organic carbon emissions.

9.3 Vertical profiles

In order to link the information of surface concentrations, aerosol composition and vertical structure, Fig. 17 presents vertical profiles for the same stations as in Fig. 16 and for
Table 10. Relative percentages of the chemical composition of the modeled surface PM$_{10}$ for each site. Values are calculated using the hourly values for the period from 1 June to 15 July 2013. For each site, the largest value is written in bold.

| Site                  | SOA (%) | Ammonium (%) | Nitrate (%) | Sulfate (%) | Sea salt (%) | PPM (%) | POM (%) | EC (%) | Dust (%) |
|-----------------------|---------|---------------|-------------|-------------|--------------|---------|---------|--------|----------|
| **AirBase coastal “background” stations** |         |               |             |             |              |         |         |        |          |

Figure 17. Vertical profiles of all modeled aerosols for 21 June 2013. Results are presented for the ADRIMED sites (Lampedusa and Cape Corsica) and some selected AirBase sites, continental and coastal stations. Note that the abscissa is different in each plot to better see the values.
may only vary with heterogeneous chemistry and deposition. For mineral dust, the size distribution may vary at emission, depending on the wind speed and following the dust production model of Alfaro and Gomes (2001). In order to directly compare observations and model results, the modeled column aerosol volume–size distribution is calculated for each model bin as in Péré et al. (2010):

$$\frac{dV}{d\log(D_p)} = \sum_{k=1}^{n_{\text{levels}}} n_{\text{levels}} \left( \frac{\sum_{c=1}^{c_{\text{nnaero}}} m_c}{\rho_c} \right) \times \Delta z_k$$

where $m_c$ is the mass concentration of particles in a volume of air, in $\mu g \text{ m}^{-3}$ for the naero modeled aerosols. $\rho_c$ is the particle density (also in $\mu g \text{ m}^{-3}$, the mass of the particle in its own volume). In this model version, all aerosols have the same density, $\rho = 1.5 \times 10^3 \text{ kg m}^{-3}$, except the mineral dust with $\rho = 2.65 \times 10^3 \text{ kg m}^{-3}$. $\Delta z_k$ the model layer thickness (for a total of $n_{\text{levels}}$ levels) and $D_{p,\text{min}}$ and $D_{p,\text{max}}$ the minimum and maximum mean mass median diameter of the $i$th bin. These diameters are converted to radii for the direct comparison with the AERONET data. The naero model species are those presented in the previous sections: SOA, ammonium, nitrate, sulfate, sea salt, PPM, POM, EC and dust.

10.2 Results

Retrieved aerosol size distributions are presented in Fig. 18 for some stations listed in Table 1: Banizoumbou, Cinzana, Cabo Verde, Izana and Lampedusa. The aerosol sizes are expressed in radius, as the original AERONET ASD data. In the figures, the scale for the volume size distribution changes for each date and site, in order to clearly see the values.

Maximum concentrations are observed and modeled in Banizoumbou and Cinzana, these stations being where the mineral dust sources are. This also explains that the size distribution is mainly constituted by a mode with $r = 1–2 \mu m$, corresponding to a dominant mode in mineral dust emissions, (Alfaro and Gomes, 2001). For these two sites, a systematic difference is observed between the model and the measurements: the main peak of the modeled coarse mode is for a radius of $\approx 1 \mu m$, when the AERONET ASD exhibits a peak for a radius of $\approx 2 \mu m$. This bias will probably induce a longer transport in the model than in reality, since the deposition velocity increases with the aerosol radius for these particles sizes (Forêt et al., 2006). These results clearly show that improvements have to be done in the size distribution of mineral dust emissions. Even if only a few figures are presented, all size distributions were analyzed and these discrepancies were observed in all cases, highlighting a systematic problem in the model representation.

After some transport of mineral dust, an important fine mode (with $r \approx 0.03 \mu m$) is modeled at Cabo Verde. This
Figure 18. Comparisons between the measured (AERONET) and modeled (CHIMERE) aerosol size distributions for the locations of Banizoumbou, Cinzana, Cabo Verde, Izana and Lampedusa. Distributions are presented for 17 and 21 June 2013, and for hours where the AERONET hourly inverted distributions are available.

fine fraction is not present in the AERONET size distribution. Far from the mineral dust sources, in Izana and Lampedusa, the comparisons of observed and modeled size distributions are poor. In Izana, the model overestimates the AERONET concentrations for all modes. In Lampedusa, observations clearly show two modes (with radius \( \approx 0.1 \) and 2 \( \mu \)m), when the model reproduces a flat distribution for 17 June and a coarse mode peak only for 21 June.

11 Conclusions

This study analyzed the ozone and aerosol tropospheric concentrations and their variability over the Euro–Mediterranean region, from 1 June to 15 July 2013. This region and period was studied within the framework of the ADRIMED project, a measurements campaign of the CHARMEX program. This analysis was performed by using measurements from the ADRIMED project (airborne measurements), routine network measurements (AIRBASE, AERONET, E-OBS) and modeling with WRF and CHIMERE. First, the model results were compared to measurements to quantify the ability of the model to restitute the spatiotemporal variability of ozone and aerosol both at the surface and in altitude. Second, the model was used to go further by analyzing the chemical composition of the aerosols. In addition, the aerosol size distribution variability between Africa and the Mediterranean area was analyzed by comparing AERONET and CHIMERE values.

It was shown that the summer 2013 was not highly polluted compared with the other years. The meteorology, namely 2 m temperature and daily precipitation amount, was characterized using E-OBS data and WRF model results. The meteorological conditions were far from drought and several precipitation events were observed and modeled. This explains a moderate ozone production (sensitive to temperature) and mean values of aerosol concentrations (sensitive to scavenging). In addition to the real situation, the model was found to underestimate the temperature (a bias of \( \approx 0-1.5 \) K over land where E-OBS data are available), contributing to slow the already low ozone production. On the other hand, the correct modeled precipitation variability helps to correctly quantify the aerosol variability, with scavenging at the right place and day.

The ozone concentrations were studied along the flight trajectories and close to the surface. If the main day-to-day variability was simulated, it was shown that the model has difficulties to reproduce the numerous ozone plumes, relatively thin but not very concentrated, flowing from west to east in Europe. When precipitation events occurred, the ozone and PM surface concentrations decreased, showing the high impact of photolysis attenuation due to cloudiness for ozone and wet scavenging for aerosols. Using the model aerosol speciation, it was shown that the main part of the PM\(_{10}\) surface concentration is composed of mineral dust. Another large fraction is due to sea salt and sulfate concentrations.

On the vertical, the mineral dust clearly dominates the total load of aerosols, when sea salt and sulfates are mainly present in the boundary layer. A focus was done on aerosol size distribution by using time series of AERONET products over numerous sites, in Africa, where the sources of mineral dust are and, in Europe, where a mix of several sources is present: local erosion, anthropogenic and biogenic emissions, vegetation fires. The ability of the model to reproduce
the aerosol size distribution was quantified and it was shown that, in Africa, the coarse mode is underestimated when, in the Euro–Mediterranean area, the fine mode is mainly overestimated by the model.

Acknowledgements. This study was partly funded by the French Ministry in charge of Ecology. We thank the SAFIRE joint laboratory and the CHARMEX program for providing us all campaign measurements used in this study. We thank the EEA for maintaining and providing the AirBase database of pollutant surface concentrations over Europe. We thank the principal investigators and their staff for establishing and maintaining the AERONET sites used in this study: Didier Tanré for Banizombou, Cabo Verde and Dakar; Bernadette Chatenet and Jean-Louis Rajot for Zinder and Cinzana; Daniela Meloni and Alcide Di Sarra for Lampedusa. We acknowledge the Service d’Observation PHOTONS/AERONET and the AERONET-ACTRIS TNA supporting the AERONET activity in Europe. Analyses and visualizations used in this study for the MODIS satellite AOD maps were produced with the Giovanni online data system, developed and maintained by the NASA GES DISC. We acknowledge the E-OBS data set from the EU-FP6 project ENSEMBLES (http://ensembles-eu.metoffice.com) and the data providers in the ECAD project (http://www.ecad.eu).
