Objectives
In order to elucidate the influence of sympathetic nerves on lumbar radiculopathy, we investigated whether sympathectomy attenuated pain behaviour and altered the electrical properties of the dorsal root ganglion (DRG) neurons in a rat model of lumbar root constriction.

Methods
Sprague-Dawley rats were divided into three experimental groups. In the root constriction group, the left L5 spinal nerve root was ligated proximal to the DRG as a lumbar radiculopathy model. In the root constriction + sympathectomy group, sympathectomy was performed after the root constriction procedure. In the control group, no procedures were performed. In order to evaluate the pain relief effect of sympathectomy, behavioural analysis using mechanical and thermal stimulation was performed. In order to evaluate the excitability of the DRG neurons, we recorded action potentials of the isolated single DRG neuron by the whole-cell patch-clamp method.

Results
In behavioural analysis, sympathectomy attenuated the mechanical allodynia and thermal hyperalgesia caused by lumbar root constriction. In electrophysiological analysis, single isolated DRG neurons with root constriction exhibited lower threshold current, more depolarised resting membrane potential, prolonged action potential duration, and more depolarisation frequency. These hyperexcitable alterations caused by root constriction were significantly attenuated in rats treated with surgical sympathectomy.

Conclusion
The present results suggest that sympathectomy attenuates lumbar radicular pain resulting from root constriction by altering the electrical property of the DRG neuron itself. Thus, the sympathetic nervous system was closely associated with lumbar radicular pain, and suppressing the activity of the sympathetic nervous system may therefore lead to pain relief.

Keywords: Lumbar radicular pain, Sympathectomy, Dorsal root ganglion, Excitability, Whole-cell patch-clamp, K+ channel

Article focus
To clarify whether sympathectomy could reduce pain behaviour and excitability of dorsal root ganglion (DRG) neuron in a rat model of lumbar radiculopathy by behavioural and electrophysiological analyses

Key messages
The sympathetic nervous system generates pain after nerve damage, although it does not influence pain generation under normal conditions. It was reported that suppressing sympathetic nerve activity reduced neuropathic pain and several mechanisms have been suggested. However, alteration of the electrical property of the DRG neurons by sympathectomy has not been well investigated

We used single isolated DRG neurons in the electrophysiological analysis, which are not affected by surrounding factors such as blood flow and effects of neurotransmitters. Therefore, the present result suggests that sympathectomy attenuates pain behaviour caused by root constriction by altering the electrical property of the DRG neuron itself.
Strengths and limitations

To our knowledge, this is the first study to investigate the alterations of the electrical property of the single isolated DRG neuron by sympathectomy in an animal model of lumbar radiculopathy.

The limitations of this study are that membrane currents were not investigated. Further studies are needed to clarify the mechanism underlying the action potential changes caused by sympathectomy.

Introduction

Lumbar radicular pain caused by lumbar disc herniation or lumbar spinal canal stenosis is one of the most common symptoms of neuropathic pain treated by orthopaedic surgeons or pain clinicians. Patients with lumbar radicular pain are usually treated with oral medication, epidural block or surgery; however, some patients are difficult to treat using these methods and are afflicted with chronic pain. Previous studies have suggested that the sympathetic nervous system plays an important role in generating chronic neuropathic pain. However, it does not generate pain under normal circumstances. In neuropathic pain, an abnormal sympathetic-somatosensory interaction is formed that leads to sympathetically maintained pain. To treat such patients, in particular those suffering from chronic pain such as complex regional pain syndrome, sympathetic nerve blocks and surgical sympathectomy are used, which are often effective.

It has been reported that sympathetic nerve fibres sprout in the dorsal root ganglion (DRG) after nerve injury, and that sympathectomy can relieve mechanical allodynia and thermal hyperalgesia in peripheral nerve injury models. In contrast, some animal studies have reported that sympathectomy does not reduce allodynia and hyperalgesia. In addition, a clinical report demonstrated that the placebo effect of phentolamine, a sympathetic blocker for painful polyneuropathies, was responsible for pain relief. In summary, the pain relief effect of sympathectomy for neuropathic pain, especially for lumbar radicular pain, has not been well investigated.

In our previous study, we investigated the influence of the sympathetic nervous system on lumbar radicular pain using a lumbar root constriction model. Immunochemical analysis showed that sympathetic nerve fibres were more abundant on the constriction side of the DRG than on the contralateral side. Norepinephrine (NE), a neurotransmitter of the sympathetic nervous system, enhances the excitability of the DRG neurons, suggesting that the sympathetic nervous system is closely related to lumbar radicular pain.

We used a model of lumbar radiculopathy and behavioural and electrophysiological analyses to investigate whether sympathectomy could attenuate pain-related behaviour and alter the electrical properties of the DRG neurons.

Materials and Methods

Experimental animals. The Sapporo Medical University Animal Care and Use Committee approved all the experimental protocols used in this study. We used a total of 60 adult male Sprague-Dawley rats weighing between 150 g and 200 g and divided them into three equal experimental groups: root constriction (RC) group, RC+ sympathectomy (Syx) group, and control group (n = 20 in each group; each comprising ten for the behavioural study and ten for the electrophysiological study).

Surgical procedures. Root constriction and sympathectomy were performed by a method previously described under a microscope on rats anaesthetised intraperitoneally with sodium pentobarbital (50 mg/kg) under sterile conditions. Each rat was placed in the prone position, and the LS-6 intervertebral space was identified. Through a midline dorsal incision at L4-S1, the paraspinal muscles were retracted to expose the left LS-6 facet joint. A left LS hemilaminectomy and LS-6 partial facetectomy were performed. The incision and muscle exposures were minimised in order to avoid invasion of the DRG neurons as much as possible. The left LS spinal nerve root and DRG were carefully exposed, and the LS spinal nerve root was tightly ligated extradurally with 8-0 nylon suture proximal to the DRG in the RC group. In the RC+Syx group, sympathectomy was immediately performed after the root constriction procedure. The animals were placed in the supine position, and later, using a transperitoneal approach, the L2 to LS sympathetic ganglia and chains on both sides were visualised by gently retracting the psoas major and resected. In the control group, no such procedures were performed.

Behavioural analysis. This was undertaken in order to evaluate mechanical allodynia and thermal hyperalgesia. In order to assess the mechanical withdrawal response, the rats were placed in a Plexiglas chamber (IITC Life Science Inc., Woodland Hills, California) measuring 18 cm \times 25 cm \times 18 cm above a wire mesh floor, which allowed full access to the hind paw, and behavioural accommodation was allowed for at least 20 minutes before the test. The mechanical withdrawal response was measured as the frequency of withdrawals of the hind paw elicited by a defined mechanical stimulus of 3.4 g using a calibrated nylon filament (Semmes-Weinstein Monofilaments; North Coast Medical Inc., San Jose, California). The mechanical stimulus was applied to the middle area between the foot pads on the plantar surface of the left (constriction side) and right (contralateral side) hind paw. Each hind paw was probed consecutively by ten tactile stimulations alternating between the left and right. Each test was repeated three times at intervals of at least 10 minutes, which resulted in each foot receiving 30 mechanical stimulations. The mechanical sensitivity was assessed by counting the total number of withdrawal responses elicited out of a total possible score of 30. The mechanical withdrawal frequency for each rat was...
expressed as the number of responses from the contralateral side (not constricted) subtracted from the number of responses from the ipsilateral side (constricted). When the mechanical sensitivity of the hind paws did not differ, the mechanical withdrawal frequency was calculated as zero. The procedure was performed two days before and three, seven, ten, 14, 21, and 28 days after surgery.

In order to assess the thermal withdrawal response, the rats were placed in a Plexiglas chamber on a glass platform and allowed to acclimatise for at least 20 minutes before the test. The thermal withdrawal response was measured as the latency of hind paw withdrawals elicited by a radiant heat source (Tail Flick Analgesia Meter; IITC Inc.), which was moved beneath an area of the hind paw that was flush against the glass. The intensity of the heat stimulus was constant throughout all experiments and adjusted to elicit a quick withdrawal reflex at a latency of approximately 6 seconds to 8 seconds in the control rats. A cut-off time of 10 seconds was set to prevent tissue damage. Each hind paw was tested five times at intervals of at least 5 minutes, alternating between the left and right. The mean withdrawal latency was calculated from the last four measurements. Consequently, the thermal withdrawal latency of each rat was defined as the latency of the contralateral response (not constricted) minus the ipsilateral response (constricted). Positive and negative scores indicated increased and decreased sensitivity of the ipsilateral hind paw, respectively. This test was performed after evaluating mechanical sensitivity. Investigators blinded to the surgical protocol of each rat performed these behavioural tests.

Electrophysiological analysis. All experiments were performed at room temperature (22°C to 24°C). At 10 to 14 days after surgery, the rats were killed. Under a stereo-microscope, the ipsilateral L5 DRG was quickly excised from the lumbar sympathetic nerves. The tissue was digested with collagenase (8 mg/mL, Type II, 034–10533; Wako Pure Chemical Industries, Tokyo, Japan) for 80 minutes in a shaking incubator (37°C, 1.5 Hz) and rinsed with Ca2+-free Tyrode’s solution at room temperature (pH 7.4 by NaOH). The excised DRG was immersed in Ca2+-free Tyrode’s solution at room temperature (pH 7.4 by KOH).

We used two protocols to perform current-clamp recordings; a short stimulation protocol (depolarising currents of 0.2 nA to 4.0 nA, 0.5 ms) and a long stimulation protocol (depolarising currents of 0.01 nA to 0.39 nA [increments of 0.02 nA], 1000 ms). In order to evaluate the excitability of the DRG neurons in the three experimental groups, we examined the electrical properties such as threshold current, threshold voltage, RMP, amplitude, AHP, APD50, and dV/dt max in the short stimulation protocol. The threshold current was defined as the minimum current required in order to evoke an AP. The threshold voltage was defined as the beginning of the upstroke of AP. The RMP was recorded 3 minutes after a stable record-

Thermal hypersensitivity also increased in the RC group increased from three to 28 days after surgery, compared with the control group, but significantly reduced in the RC+Syx group over the same time period. The mechanical withdrawal frequencies were not completely reduced in the RC+Syx group compared with the control group at three, seven, or ten days after surgery, but there was no significant difference between the RC+Syx and control groups at 14, 21, and 28 days after surgery (Fig. 1a).

Thermal hypersensitivity also increased in the RC group compared with the control group from three to 28 days after surgery and was significantly reduced in the RC+Syx group. The withdrawal latencies were not completely reduced in the RC+Syx group compared with the control group at three, seven, ten, or 14 days after surgery. No significant difference between the RC+Syx and control groups at 21 and 28 days (Fig. 1b) was observed.
Electrophysiological analysis. The action potentials (APs) of the DRG neurons in the three experimental groups (n = 10 each) recorded by the whole-cell patch-clamp method are shown in Figure 2. In the RC group, the DRG neurons exhibited a significantly lower threshold current, more depolarised resting membrane potential (RMP), prolonged action potential duration at 50% repolarisation (APD50), and greater maximum (max) spike count compared with the control group. These hyperexcitable alterations caused by root constriction were significantly attenuated by surgical sympathectomy. There were no significant changes in any of the other parameters tested such as threshold voltage, amplitude and after hyperpolarisation (AHP) (* p < 0.05 versus control; † p < 0.05 versus RC+Syx).
the three groups. Changes in the discharge pattern and the excitability of the DRG neurons in the long stimulation protocol are shown in Figure 4. In the RC+Syx group, the mean value of the max spike count was 5.0 (SEM 1.5), which was significantly smaller than the mean of 13.7 (SEM 1.7) in the RC group.

Discussion

The sympathetic nervous system is considered to be one of the most important factors in the generation of neuropathic pain. McLachlan et al reported that in the sciatic nerve ligation model, sympathetic nerve fibres increased in the corresponding DRGs and sprouted to the DRG somata, forming basket-like structures. Other studies also reported that sympathetic sprouting occurred in various neuropathic pain models. In addition, Shinder et al demonstrated that sympathetic basketskeins were observed in the DRGs excised from human neuropathic pain patients. We have shown that sympathetic nerve fibres sprouted to the DRG myelin sheaths in the DRG neurons in our root constriction model. This implies that the sympathetic nervous system has a direct and/or indirect influence on the DRG, causing not only peripheral nerve injury but also lumbar root damage. Thus, the sympathetic nervous system is closely associated with neuropathic pain, and suppressing the activity of the sympathetic nervous system might therefore lead to pain relief.

In the present behavioural study, surgical sympathectomy significantly attenuated mechanical allodynia and thermal hyperalgesia caused by root constriction. However, in the RC+Syx group, mechanical and thermal hypersensitivities were not reduced significantly compared with the control group, but they were significantly attenuated compared to the RC group. Sympathectomy may be insufficient to alleviate radicular pain, because...
not only the sympathetic nervous system but also other factors such as the inflammatory response and effects of neurotransmitters are related to radicular pain. Meanwhile, several studies have also reported that sympathetic tone reduces mechanical allodynia and thermal hyperalgesia in various animal pain models. Clinical reports have shown that a sympathetic nerve block reduces lumbar radicular pain and sympathetic tone increases intraradicular, cauda equina, and sciatic nerve blood flow. It has also been suggested that the recovery of reduced DRG blood flow might prevent allodynia in a radicular pain model. Sekiguchi et al reported that sympathetic tone reduced mechanical allodynia, tumor necrosis factor-alpha (TNF-α) expression, and DRG neuron apoptosis following nerve root crush injury. Chen et al showed that surgical and chemical sympathectomy significantly attenuated bee venom-induced mechanical hyperalgesia and inflammatory response. Therefore, sympathectomy may exert its analgesic effect through several mechanisms.

In the present electrophysiological study, the root constriction DRG neurons exhibited a lower threshold current, more depolarised RMP, prolonged AP duration, and max spike count. Kirita et al reported that the Na+ current was significantly increased in the root constriction neurons and lumbar radicular pain may be associated with increased excitability of the involved DRG neurons. Another report showed that the fast Na+ current in the DRGs increased in a peripheral nerve injury model. The present electrophysiological analysis showed that surgical sympathectomy significantly attenuated the hyperexcitability of the root constriction DRG neurons. In particular, more hyperpolarised RMP and reduced AP duration in the RC+Syx group may suggest that outward currents were increased by K+ channel activity, because RMP and AP duration are both significantly dependent on K+ channel activity. Previous reports demonstrated that an ATP-sensitive K+ channel activator reversed the hyperexcitability induced by bradykinin in the DRG neurons and expression of inwardly rectifying K+ channels in chronically compressed DRG neurons suppressed neuronal excitability and hyperalgesia. These reports suggest that alteration in a few types of K+ channels is one of the important factors causing neuropathic pain. In addition, Xie et al reported that K+ channel blockers increase the spontaneous activity of the DRG neuron and sympathetic sprouting, and Honma et al reported that NE inhibits Ca2+-activated K+ channel activity and outward K+ currents leading to cell membrane depolarisation. The results of this study along with previous reports imply that the sympathetic nerves contribute to pain by altering the K+ channels.

One of the main advantages of this study was the use of isolated DRG neurons in the electrophysiological analysis. Isolated DRG neurons are not influenced by their surrounding factors such as blood flow and presence of neurotransmitters. Therefore, the results of the present study show that root constriction altered the DRG neuron itself, and this alteration was inhibited by sympathectomy. This result may be evidence demonstrating that the sympathetic nervous system is one of the key factors in pain generation caused by nerve root damage as a result of alterations in the DRG neuron itself. In fact, the excitability of isolated DRG neurons from normal rats did not alter with NE application, but significantly increased in the DRG neurons with root constriction. These findings indicate that the DRG neuron itself is changed by root constriction. In addition, DRG neuron hypersensitivity has been improved by sympathectomy immediately after root constriction. This result suggests that the sympathetic nervous system plays an important role in altering the DRG neuron as a result of root constriction, and that suppressing the activity of the sympathetic nerve at an early stage after root constriction may be important in suppressing the development of a pain cycle because of root damage.

Membrane currents were not investigated in the present study. AP changes such as hyperpolarised RMP and reduced AP duration observed in the RC+Syx group might be caused not only by alterations in the K+ channel but also by another ion channel, such as the Cl– channel. Further studies are needed to clarify the mechanism underlying the AP changes caused by sympathectomy.

Conclusions. In behavioural analysis, sympathectomy significantly attenuated mechanical allodynia and thermal hyperalgesia caused by root constriction, but the pain relief effect was not complete. In electrophysiological analysis, hyperexcitable alterations of the DRG neurons caused by root constriction such as lower threshold current, more depolarised RMP, prolonged APD50, and max spike count were significantly attenuated by surgical sympathectomy. We used isolated DRG neurons, which are not affected by surrounding factors such as blood flow and presence of neurotransmitters. Therefore, the present results suggest that sympathectomy attenuates lumbar radicular pain caused by root constriction by altering the electrical property of the DRG neuron itself. Sympathectomy hyperpolarised the RMP of the RC neurons and shortened the AP duration. The present results suggest that sympathectomy attenuates excitability of the DRG neurons by altering the K+ channels and may contribute to pain relief in a lumbar radiculopathy model.
