Abstract

In a single-center review of antibiotic prescribing in COVID-19 patients, 10% of patients received antimicrobials, and inpatients encountered had the highest rate and spectrum of prescribing. Prescribing rate, spectrum, and duration appeared to increase with disease severity in inpatients. Antimicrobial prescribing in patients managed in ambulatory encounters was less common.

(Received 18 May 2020; accepted 21 July 2020; electronically published 24 July 2020)

Detailed data surrounding antimicrobial usage in patients with coronavirus disease 2019 (COVID-19) are lacking. To date, our institution has not been an epicenter of the pandemic. Thus, the slow but consistent flow of cases has allowed for careful consideration of each case for candidacy for clinical trial enrollment, and formal infectious diseases consultation is provided for all inpatient encounters. Despite low local prevalence at the time, we found a cursory review of antibiotic prescribing early in the pandemic to be imperative, setting the stage for adjustment of antimicrobial stewardship practices if a future surge is to be observed. As we enter further into the realm of the unknown, data continue to emerge outlining indirect outcomes of COVID-19. One such outcome is the rate of coinfection with other pathogens and the associated use of antimicrobials. (1) Currently, data are sparse concerning antimicrobial management strategies for COVID-19. One review posited that coinfection during COVID-19 is rare; however, antimicrobial use among inpatients is common. (2) Some organizations have published guidelines to help streamline antimicrobial use in patients with pneumonia during the COVID-19 pandemic. (3) Despite the acute COVID-19 pandemic, antimicrobial resistance continues to be an ongoing and silent epidemic, accounting for ~3 million cases and ~35,000 deaths annually. (4) As the pandemic evolves, consideration should be given to evaluating the impact of potential excessive and/or unnecessary antimicrobial use in COVID-19 patients to mitigate unintended consequences, including adverse effects, unnecessary cost, and antimicrobial resistance.

Methods

We retrospectively evaluated local patients diagnosed with COVID-19 at our large, academic, tertiary-care center during an inpatient, emergency department (ED), or outpatient encounter to analyze the prevalence, number of agents, spectrum of activity, and duration of antimicrobial therapy. We included patients ≥18 years of age with a confirmed case of COVID-19 (ie, a positive real-time polymerase chain reaction [RT-PCR] assay for severe acute respiratory coronavirus virus 2 [SARS-CoV-2]) diagnosed locally between March 1 and April 28, 2020. Only local patients were included to maintain uniformity of practice and review and to better understand local prescribing practices. Patients were excluded if they had not given consent for data utilization through the Minnesota research authorization. Patients were identified with a report of positive RT-PCR generated from the electronic health record. Patients were assigned to groups according to the encounter type during which they were diagnosed with COVID-19 (ie, inpatient, ED, or outpatient).

Antimicrobial prescribing data were included when employed for a suspected or confirmed respiratory tract infection. Antimicrobial utilization was evaluated by overall prescribing rate, days of therapy (DOT), DOT per antimicrobial day, and duration of therapy. Inpatients discharged on oral antimicrobials were included in overall antimicrobial metrics. For patients managed in ED or outpatient encounters, antimicrobials prescribed for a respiratory indication within 14 days of the testing date were reported. To provide assessment of the antimicrobial spectrum across various encounter types, an antimicrobial spectrum score developed by Gerber et al5

was applied to antimicrobial use data. Total spectrum scores were calculated and normalized by duration of therapy to determine the antimicrobial spectrum score per total antimicrobial day.

Results

In total, 346 patients met inclusion criteria (Table 1). The mean age of the total population was 45 years, and 49% were men. Inpatient encounters accounted for 39 patients (11.3%): 7 cases (17.9%) were mild, 17 cases (43.6%) were moderate, and 15 cases (38.5%) were severe. Also, 4 inpatients remained admitted at the time of article submission, with data collected through May 5, 2020. Ambulatory encounters accounted for 307 patients, with 20 (5.8%) diagnosed in the ED and 287 (82.9%) diagnosed as outpatients. All patients diagnosed as outpatients were diagnosed by collection of specimens in a drive-through testing station with follow-up by virtual or telephone encounters. Of all patients initially managed in the ambulatory setting, 25 (8%) had follow-up ED encounters and 12 (4%) were admitted as inpatients before May 5, 2020.

Respiratory cultures were collected from 8 patients, all in the inpatient cohort: 6 were collected by tracheal aspiration and 2 by expectorated sputum. A causative pathogen (methicillin-sensitive Staphylococcus aureus) was only identified in 1 culture. Respiratory viral panels were collected in 4 patients and from the entire inpatient cohort, none of which identified a coinfecting pathogen. Influenza testing was performed in 12 inpatients (31%), 2 outpatients (1%), and no patients in the ED cohort. All influenza tests were negative.

Across the entire cohort, 10% of patients received antimicrobial therapy for a mean duration of 5.7 days, with a mean spectrum score per DOT of 8 (Table 2). Antimicrobials were administered in 59% of all inpatients with rates of 29%, 47%, and 87% for mild, moderate, and severe cases, respectively. The average number of DOT per antimicrobial day in all inpatients was 1.65: 1.18 for mild cases, 1.29 for moderate cases, and 1.84 for severe cases, respectively. The mean spectrum score per day of antimicrobial therapy was 9.2 in all inpatients and increased with disease severity, with mean scores per day of therapy of 8.1, 8.4, and 9.9 in mild, moderate, and severe cases, respectively. The mean duration of therapy in inpatients was 5.4 days: 5.5 days for mild cases, 3.5 days for moderate cases, and 6.5 days for severe cases.

Antimicrobial prescribing rates were considerably lower for ambulatory patients (3% overall), with ED and outpatient encounters demonstrating prescribing rates of 15% and 2%, respectively. Ambulatory antimicrobials were prescribed for a mean duration of 6.3 days: 6.8 days for ED encounters and 6 days for outpatient encounters. Ambulatory regimens generally contained fewer antimicrobials (1.35 DOT per antimicrobial day) and appeared to have narrower spectra (mean spectrum score per day of antimicrobial

| Table 1. Population Demographics |
|----------------------------------|--------------------------------|
| Characteristics                  | Inpatient, %a                  | Ambulatory, %a |

aUnits unless otherwise specified.
During the COVID-19 pandemic, a reasonable amount of apprehension from providers regarding withholding antibiotics is expected, and vigilance by antimicrobial stewardship teams to identify and intervene upon unnecessary or inappropriate use is essential for mitigation of their unintended adverse consequences. The overall incidence of bacterial coinfection in patients with COVID-19 seems to be ~10%, based on various studies emerging from China, Italy, and the United States. Despite this fact, the overall rate of antimicrobial usage, especially among inpatients, appears to be high. A review of 18 studies reporting antimicrobial use in patients with COVID-19 found the prescribing rate to be 72%, with no antimicrobial stewardship interventions described in these studies to combat overuse. Data demonstrating clinical benefit of antibiotics as part of the routine management of patients with COVID-19 are lacking; retrospective cohort studies report similar or higher rates of antibiotic use in COVID-19 nonsurvivors compared to survivors.

With concerns being raised for a wave of antimicrobial resistance following this pandemic, we sought to evaluate our early inpatient prescribing data to determine whether it correlated with other available reports. We identified similar rates of antimicrobial use in inpatients as seen in other recent studies, and, of unique value, we identified that very few outpatients received antimicrobials when diagnosed with COVID-19. We also found that coinfections with other pathogens were infrequent. Overall, antimicrobials were prescribed in 10% of patients. Inpatient admissions led to a higher prescription rates (59%) compared to ambulatory encounters (3%). We applied a previously described spectrum score to demonstrate the spectrum of antimicrobials used. This score assigns each antimicrobial a numerical score based on its spectrum of activity. In our review, when antimicrobials were prescribed, the duration of therapy appeared similar between inpatient and ambulatory encounters, but inpatients tended to receive broader-spectrum agents, as demonstrated by the mean spectrum score per day of antimicrobial therapy (9.2 for inpatients vs 4.9 for outpatients). Among the inpatient cohort, patients with severe disease received the broadest spectrum agents and longest durations of antimicrobials. Among the outpatient cohort, in addition to the relative infrequency of outpatient antimicrobial prescribing, narrower-spectrum antimicrobials were used in comparison to inpatient regimens.

Although comparative data pertaining to outpatient antimicrobial prescribing in COVID-19 patients are not available, our outpatient results represent an important finding, given increased attention to ambulatory antimicrobial stewardship with the new Joint Commission regulatory standards in 2020. Aside from COVID-19, other studies have evaluated antimicrobial prescribing patterns in outpatient settings for respiratory indications unlikely

### Table 2. Antimicrobial Utilization

| Antimicrobial Metric | Full Cohort (n = 346) | Inpatient | Ambulatory |
|----------------------|----------------------|-----------|------------|
|                      | All (n = 307)        | Moderate (n = 15) | All (n = 287) |
| Antibiotics Rx, no. (%) | 33 (10)           | 23 (59)  | 2 (29)   |
| Duration, mean d ±SD    | 5.7 ± 2.7          | 3.5 ± 2.7 | 6.5 ± 2.3 |
| Mean spectrum score per antimicrobial day ±SD | 8.0 ± 3.5        | 8.1 ± 7.0 | 9.9 ± 2.7 |
| Total DOT/antimicrobial days | 1.59          | 1.29    | 1.84 |
| Total DOT              | 287                | 36      | 156 |
| Ceftriaxone DOT        | 53                 | 12      | 41 |
| Cefdinir DOT           | 20                 | 0       | 0 |
| Cefazolin DOT          | 2                  | 0       | 0 |
| Azithromycin DOT       | 74                 | 13      | 30 |
| Doxycycline DOT        | 15                 | 1       | 9 |
| Vancomycin DOT         | 26                 | 2       | 22 |
| Piperacillin/Tazobactam DOT | 28            | 8       | 20 |
| Cefepime DOT           | 31                 | 1       | 30 |
| Metronidazole DOT      | 2                  | 0       | 2 |
| Amoxicillin DOT        | 5                  | 0       | 0 |
| Amoxicillin/Clavulanate DOT | 0                | 0       | 0 |
| Penicillin DOT         | 10                 | 0       | 0 |
| Cefuroxime DOT         | 2                  | 0       | 0 |
| Cefadroxil DOT         | 7                  | 0       | 0 |
| Levofloxacin DOT       | 12                 | 5       | 7 |

Note: SD, standard deviation; Rx, prescription; DOT, days of therapy.
to benefit from antimicrobials and found prescribing rates of ~21%. Factors that influence inappropriate prescribing of antimicrobials include diagnostic uncertainty, time pressures, and perception of patient pressure antimicrobial prescribing. A potential hypothesis for our low rate of antimicrobial prescribing in the outpatient setting is that ambulatory encounters involved cases that were milder, for which the positive RT-PCR provided a level of diagnostic certainty, and for which time-related and patient-driven antibiotic prescribing pressures may have been reduced given virtual or telephone follow-up. Additionally, at our institution, the infectious disease division played an active role in logistical and resource support for managing ambulatory COVID-19 encounters, likely easing provider concerns pertaining to withholding antibiotics. As antimicrobial stewardship teams look to optimize antimicrobial utilization in COVID-19, our findings suggest that efforts should be focused on the inpatient and ED settings. Attempts to further optimize outpatient antimicrobial prescribing in COVID-19 cases, where ID specialists are already actively involved likely represents a scenario in which effort could far exceed the potential impact.

Our study has several limitations. Most importantly, our center is a large academic center in a relatively small community located in an area of low disease prevalence, which may limit external validity. Laboratory studies testing for the presence of coinfection were not employed in all patients. Thus, coinfection rates reported may not represent the absolute rates that may have been observed had testing been widely utilized. Also, these data were collected from patients seen very early on in the pandemic, when information regarding coinfection with bacterial pathogens was sparse.

Detailed data specific to antimicrobial use in patients with COVID-19 across the care continuum are currently limited. When reported, specific antimicrobial utilization metrics are often missing. A pertinent strength of our study is the application of spectrum scoring in addition to other common antimicrobial use metrics. Most importantly, we have described data pertaining to antimicrobial utilization in 287 patients diagnosed and managed as outpatients. An understanding of antimicrobial prescribing rates across the continuum of care, as reported here, will allow facilities to carefully craft targeted antimicrobial stewardship strategies to contribute to the minimization of unnecessary and/or inappropriate antimicrobials in patients with COVID-19.

At our center, increased prescribing rates and broader spectrums of antimicrobial activity seemed to be used in patients with greater disease severity and those requiring a higher level of care. However, increased antimicrobial utilization did not coincide with increased observation of bacterial coinfection. We are reassured to know that inpatient management of nonsevere cases and outpatient management of mild cases did not involve widespread antimicrobial usage. Management of COVID-19 patients must reflect available and evolving evidence. Bacterial coinfection seems to be rare, even more so in areas of low prevalence. Routine use of broad-spectrum agents and long durations of antimicrobials in patients with COVID-19 are likely unnecessary and could contribute to the epidemic of antimicrobial resistance. Larger studies across multiple institutions and geographic regions are needed to further explore this subject and to define optimal antimicrobial stewardship strategies.

Acknowledgments. We would like to acknowledge the Mayo Clinic Rochester Infectious Diseases COVID-19 Team and the Mayo Clinic Rochester Antimicrobial Stewardship Team for their excellent care of patients with COVID-19 and ongoing commitment to the careful utilization of antimicrobials.

Financial support. No funding was received in support of this project.
