Plasmon-Enhanced Photocurrent using Gold Nanoparticles on a Three-Dimensional TiO$_2$ Nanowire-Web Electrode

Yin-Cheng Yen, Jau-An Chen, Sheng Ou, Yi-Shin Chen & Kuan-Jiuh Lin

In this study, an anatase/rutile mixed-phase titanium dioxide (TiO$_2$) hierarchical network deposited with Au nanoparticles (Au/TiO$_2$ ARHN) was synthesized using a facile hydrothermal method followed by a simple calcination step. Such a unique structure was designed for improving the light harvest, charge transportation/separation, and the performance of photo-electro-chemical (PEC) cells. The properties of the as-synthesized Au/TiO$_2$ ARHN in PEC cells were investigated by electrochemical measurements using a three-electrode system in a 1 M NaOH electrolyte. Remarkably, a 4.5-folds enhancement of the photocurrent for Au/TiO$_2$ ARHN was observed as compared to that for TiO$_2$ nanowire (NW), under AM1.5G solar illumination, suggesting its potential application in PEC cells. A mechanism has been proposed to explain the high photocurrent of Au/TiO$_2$ ARHN in PEC water splitting.

Honda and Fujishima elucidated the possibility of water splitting using TiO$_2$ as electrode$^1$. Since then, various TiO$_2$ nano-architectonic topographies have been greatly desired for enhancing the performance of PEC cells$^2$–$^8$. In general, a predominant PEC cell relies on two factors: the efficient usage of solar energy and the instant transportation/separation of charges$^8$. Hence, the development of nano-sized photo-active semiconductors to satisfy the requirements has been a long-standing objective in the research of PEC cells, especially for one-dimensional TiO$_2$ due to its superior charge transport property$^1$$^9$. To date, many hierarchical TiO$_2$ nanostructures based on nanowires (NWs) and nanotubes (NTs) have been synthesized for enhanced photo-electric efficiency in solar energy harvesting, conversion, and pollutant purification$^{11}$–$^{13}$. Such a heterojunction nanostructure would stagger energy levels and scatter incident light to enlarge light absorption in the UV region$^{14}$. However, the strategies for fabricating hierarchical TiO$_2$ nanostructures have the disadvantages of an extremely time-consuming process, specific/highly expensive fabricating apparatus and back-side illumination, thus making it economically non-competitive$^{15}$–$^{25}$.

Recently, to expand the TiO$_2$ optical adsorption spectrum from the UV into the visible region, plasmonic electrodes composed of Au/TiO$_2$ nano-architectonic topographies have been developed with localized surface plasmon resonance (LSPR) property$^{26}$–$^{35}$. However, most of these reports focus on the discussion of the relationship between particle size/shape/distance/concentration and the photo-electrochemical performance$^{28}$–$^{30}$, $^{32}$–$^{35}$. Especially, one novel example of demonstrating the influence of TiO$_2$ nanostructure on the LSPR property was reported by Wang et al.$^{36}$. An Au/TiO$_2$/Au nanostructure with a 5-nm-thick TiO$_2$ middle layer was synthesized which resulted in a maximum 38-fold enhancement of the electric field density of LSPR and about 3-fold improvement of the photocurrent in a wavelength range of 400–650 nm. The enhanced performance is mainly arising from the thickness of TiO$_2$ satisfying the requirement for generating the coupling effect between the oppositely aligned and nearly touching Au NPs on TiO$_2$ nanosheet. However, the longer time (4 days) required to synthesize the TiO$_2$ nanostructures and the non-transparency of the Au/TiO$_2$/Au film limit their application. Furthermore, there is limited knowledge on how to design and synthesize a TiO$_2$ nanostructured film on a transparent substrate by a simple yet effective method. Therefore, the aim of this study is to provide a novel strategy for building a new TiO$_2$ nanostructure to intensify the coupling effect between Au NPs that significantly enhances the photoelectric conversion.

Herein, a three-dimensional (3D) web constructed by Au plasmonic NPs on TiO$_2$ anatase/rutile hierarchical network (Au/TiO$_2$ ARHN) is proposed, which is schematically shown in Fig. 1. In order to strengthen the
electromagnetic coupling of the Au NPs, the solid support—TiO2 NWs connected with TiO2 threads—was synthesized by a two-step hydrothermal process. When tested in the PEC experiment, the TiO2 ARHN and Au/TiO2 ARHN exhibited 1.5 times and 4.5 times higher photocurrent than TiO2 NWs.

Results and Discussion

Figure 2 schematically depicts the three-step fabrication process of reproducible Au/TiO2 ARHN. Figure 3a represents a top-view SEM image of the TiO2 NWs. The light-gray needle-like regions in the SEM image represent the TiO2 NWs and the dark regions are the underlying FTO substrate. A cross-sectional SEM image of the NWs (Fig. 3b) shows that the thickness of TiO2 layer is ~1 μm and the NWs have an average diameter of 40 nm. XRD patterns of the TiO2 NWs show predominantly rutile phase with preferential orientation of (110) (Supplementary Fig. 1). The top-view and cross-sectional SEM image of the TiO2 ARHN (Fig. 3c,d) shows that the TiO2 threads are bridged with the TiO2 NWs to form a 3D hierarchical network. Nest-like porous cavities with diameters of a few hundred nanometers are clearly observed and the diameters of the threads are ~10 nm. The XRD patterns and Raman spectra show that the threads belong to the anatase phase (Supplementary Figs 2 and 3). The top-view SEM image of the Au/TiO2 ARHN is shown in Fig. 3e. The white dot regions in the SEM represent the Au NPs. The size distribution histograms of Au NPs show an average particle size of 15 nm (Fig. 3f).

To investigate the formation mechanism of TiO2 ARHN, a series of experiments were performed. Firstly, we failed to obtain TiO2 ARHN without TiCl4 treatment. We found that TiO2 threads cannot grow on TiO2 NWs with a smooth surface. Secondly, in the absence of the Ti film in step 2 (in Fig. 2), only TiO2 NWs were observed. These findings suggest that both TiCl4 treatment and the formation of the Ti layer for the formation of TiO2 ARHN are indispensable. Therefore, we propose that small TiO2 seed crystals grow on the surface of TiO2 NWs after TiCl4 treatment, which leads to a rough surface for the growth of TiO2 threads. Moreover, during alkali
hydrothermal process, the Ti layers can generate large amounts of Ti-containing species\textsuperscript{37,38} as precursors that can deposit on the TiO\textsubscript{2} seeds and produce a network structure.

To evaluate the enhanced PEC performance of the designed Au/TiO\textsubscript{2} ARHN, the linear sweep voltamograms and the photocurrent-versus-time (I-t curve) of TiO\textsubscript{2} NW and TiO\textsubscript{2} ARHN with/without Au NPs were conducted under AM 1.5 G simulated solar illumination, as shown in Fig. 4. The measured photocurrent was normalized to the sample area to obtain the photocurrent density for comparison. As presented in Fig. 4a, the TiO\textsubscript{2} NW electrode produced a photocurrent density of \(4 \times 10^{-5} \text{A cm}^{-2}\) at 0.23 V vs. Ag/AgCl, which is the potential often chosen as a metric to evaluate the performance of photoanodes as it corresponds to the water oxidation potential\textsuperscript{4}. The low photocurrent density is attributed to the limit of wide band-gap characteristics of TiO\textsubscript{2} (3.2 eV for anatase\textsuperscript{39} and 3.0 eV for rutile\textsuperscript{40}), due to which only UV light can be used in the PEC water splitting system. The photocurrent was enhanced for the TiO\textsubscript{2} ARHN (\(6 \times 10^{-5} \text{A cm}^{-2}\)) when compared with TiO\textsubscript{2} NW, with an enhancement factor of 1.5. As expected, a significant photocurrent density enhancement was clearly observed on the Au/TiO\textsubscript{2} ARHN, having a photocurrent density of \(1.8 \times 10^{-4} \text{A cm}^{-2}\). As compared to TiO\textsubscript{2} NW, a photocurrent enhancement higher than 4.5 times was achieved. From Fig. 4b, all electrode represent a good reproducibility and stability as the illumination was turned on and off. Furthermore, the sharp spike in the photocurrent during the on/off illumination cycles demonstrates the predominant transport of photogenerated electrons in the designed TiO\textsubscript{2} structure\textsuperscript{41}.

Figure 3. FESEM images. (a,c,e) top images of top TiO\textsubscript{2} NW, TiO\textsubscript{2} ARHN and Au/TiO\textsubscript{2} ARHN, respectively; (b,d) cross-sectional images of TiO\textsubscript{2} NW and TiO\textsubscript{2} ARHN; (f) the size distribution of Au NPs.
We suggest the enhanced photocurrent of TiO₂ ARHN electrode could be attributed to better photocatalytic activity, due to increased surface area, or better light harvest efficiency, due to the hierarchical network structure. Therefore, the dye absorption/desorption experiment and UV-visible spectrum measurement were performed to verify it. Here, dye N719 was chosen as an adsorbate to execute dye absorption/desorption experiment due to it could be monolayer absorbed on the surface of TiO₂. Therefore, we can evaluate the related surface area via measuring the absorption of N719 dye which detached from TiO₂ structure. As shown in Fig. 5, there are three absorbed peak of N719 located on 310 nm, 370 nm and 505 nm, respectively. It is observed that the absorption of detached N719 solution based on TiO₂ ARHN is obviously larger than TiO₂ NW on entire spectrum. It represents the surface area of TiO₂ ARHN is related larger than TiO₂ NW due to there are more dye absorbed on TiO₂ ARHN. Based on the result, we make a sure that the high surface area of TiO₂ ARHN is a reasonable reason which brings to a high photoactivity on PEC measurement.

Furthermore, the UV-visible absorption spectra of the TiO₂ NW and TiO₂ ARHN with/without Au NPs are shown in Fig. 6. TiO₂ NW exhibits a stronger absorption at the wavelengths below 400 nm due to electron transitions of TiO₂ from the valence band to the conduction band. In addition, the absorption spectra of TiO₂ ARHN showed an enhanced absorption in the entire spectral range as compared with TiO₂ NW, which is attributed to the scattering effect in the ARHN structure; this also explains the increased photocurrent in the TiO₂ ARHN. With deposited Au NPs, the absorption show a significantly enhancement on visible range which is driven by the LSPR absorption. From incident photon-to-electron conversion efficiency (IPCE) measurement (Supplementary Fig. 4), it demonstrates that such an absorption successfully boosts the PEC performance in the region from 400 nm to 700 nm.

In this work, a LSPR peak for the Au NPs with average size of 15 nm centered at around 540 nm. For Au NPs of size 10–20 nm, the absorption peak of plasmon resonance is usually located at 520–525 nm. A redshift of 15–20 nm of the plasmon resonance peak was observed as compared to previous reports. This may be attributed to the TiO₂ changing the surrounding dielectric property of Au NPs (Au NPs well deposited and in contact with TiO₂ surface) and the enhancement of electromagnetic field of LSPR. It has been reported that the high electromagnetic field of LSPR and strong coupling between Au NPs and TiO₂ will benefit the plasmon-induced charge transportation and separation, enabling SPR-enhanced photocatalysis. Typically, the LSPR-induced charge separation at the interface between the Au NPs and TiO₂ can occur by transferring the energy contained in the oscillating electrons or local plasmonic field from Au NPs to TiO₂ through direct electron transfer, also known as photoinduced electron transfer. This process is illustrated in Fig. 7, where the Au NPs absorb light and transfer the energy to the TiO₂, resulting in the separation of electron-hole pairs.

Figure 5. UV-Vis spectra of desorbed N719 solution.
as hot electron injection\textsuperscript{47,48}. Higher electromagnetic field generates more hot electron\textsuperscript{49,50}. In order to verify our assumption, the design of TiO\textsubscript{2} ARHN is helpful to improve electromagnetic field as compared to NWs, the PEC measurement was performed to check the hot electron effect. Figure 7 shows the I−t curve measured under visible-light illumination. From Fig. 7, it is obvious that the photocurrent of Au/TiO\textsubscript{2} ARHN is two times higher than Au/TiO\textsubscript{2} NW. It means that the high plasmon electromagnetic field of Au/TiO\textsubscript{2} ARHN results in a high hot-electron current. Therefore, we confirm that the design of TiO\textsubscript{2} ARHN successfully provides a model for strengthening LSPR ability and demonstrates a remarkable enhancement on PEC performance.

In this study, we are further interested the effectiveness of density effect and size effect on the performance of photo electrochemical property. The related data and discussion were shown in Supplementary Information. In addition, the stability test and Faradaic efficiency were obtained. Under continuously illumination for 10800 seconds (equal to 3 hr), the photocurrent density was decrease from 1.8×10^{-4} A/cm\textsuperscript{2} to 1.5×10^{-4} A/cm\textsuperscript{2} in the case of Au/TiO\textsubscript{2} ARHN, as shown in Fig. 8a. This photocurrent decay is similar to previous report\textsuperscript{51}. We suggest it could be attributed to photo induced corrosion which competes with water oxidation reaction\textsuperscript{51}. However, such a corrosion could be suppress by surface treatment of TiO\textsubscript{2} nanostructure or use of sacrificial reagent/catalyst for longstand- ing application\textsuperscript{51}. From Fig. 8b, the calculated Faradaic efficiency exceed 90% and 85% for TiO\textsubscript{2} ARHN and Au/ TiO\textsubscript{2} ARHN, respectively. The high value of Faradaic efficiency of oxygen gas during 10hr demonstrated that the photo generated current indeed utilized for water oxidation. Also, we could observe hydrogen gas from real picture as shown inset diagram in Fig. 8c. Therefore, we propose the electron transfer mechanism in Au/TiO\textsubscript{2} ARHN system as shown in Fig. 8c. Under illumination, Au NPs absorb visible light, generating the energetic hot electrons from the process of SP excitation, and injecting them into the conduction band of the adjacent TiO\textsubscript{2} (green arrow). Simultaneously, the UV light is absorbed by TiO\textsubscript{2}, producing a photo-excited electron and a hole (black arrow). The plasmon-induced electromagnetic field promotes the separation of photogenerated electrons and holes. Furthermore, as illustrated, the energy bands of anatase and rutile are different which provides a driving force to promote electron transfer from anatase to rutile (blue arrow). Finally, the electrons transferred to the cathode (Pt) react with H\textsuperscript{+} ions and produce H\textsubscript{2} (pink arrow) whereas the holes present in the anode oxidize H\textsubscript{2}O and generate O\textsubscript{2}.

Figure 7. I−t curves collected at 0 V versus Ag/AgCl for Au/TiO\textsubscript{2} NW and Au/TiO\textsubscript{2} ARHN electrode under visible light illumination (using a cutoff filter with a wavelength of 400 nm).
In conclusion, this work demonstrates a plasmon-induced effect on a designed 3D web architecture constructed from rutile TiO2 NWs, anatase TiO2 threads and Au NPs. Such a nanostructure was achieved for the first time through a simple and inexpensive hydrothermal procedure followed by calcination. The PEC performance tests, reveal that the photocurrent of Au/TiO2 ARHN was 4.5 times greater than that of the TiO2 NW photocathode. The observed optical properties and dark current measurements confirm that the excellent PEC performance of Au/TiO2 ARHN was due to three reasons: (1) the high surface area of TiO2 ARHN that increase the photoactive center, (2) the scattering effect in the TiO2 ARHN and the LSPR properties of Au NPs that enhanced the light harvest, (3) the strength coupling effect between Au NPs and TiO2 nanostructure that accelerated the charge transportation and separation. The mechanism of charge transportation in the Au/TiO2 ARHN was proposed based on our findings. Practical use of the Au/TiO2 ARHN was demonstrated to indicate their significant potential for use in photoelectric conversion system.

Methods

Materials. F:SnO2 (FTO) (1.5 cm × 3 cm, TEC-7, 7 ohm/sq., 2.2 mm thick) was used as the substrate for growth of the TiO2 film. All chemicals were used without further purification. Sodium hydroxide (NaOH, 99%), titanium tetrachloride (TiCl4, 99%), 2-butanone (C4H8O, >99%), hydrochloric acid (HCl, 12 M) and nitric acid (HNO3, 65%) were purchased from Merck. Tetrabutyl titanate (C16H36O4Ti, >97%) and ruthenium 535 bis-TBA (N719 dye) were obtained from Aldrich and Solaronix, respectively.

Hydrothermal synthesis of TiO2 NWs on FTO substrates. First, FTO was cleaned by ultrasonic agitation in a mixture of ethanol, acetone and deionized water (volume ratio of 1:1:1) for 15 min. The FTO substrates were immersed in an aqueous of 0.5 M TiCl4 at 80 °C for 30 min, followed by heat treatment at 500 °C for 30 min to yield a thin TiO2 layer. The TiCl4-treated substrates were then suspended in a reagent solution containing 6 mL HCl, 6 mL 2-butanone and 0.6 mL tetrabutyl titanate in a Teflon vessel. The Teflon vessel was sealed in an autoclave and heated at 200 °C for 1.5 h. After annealing at 500 °C for 30 min resulted in the growth of crystalline TiO2 NWs on FTO substrates.

Hydrothermal synthesis of TiO2 ARHN on FTO substrates. The TiO2 NW substrate (without calcination) was first treated with TiCl4 solution as mentioned above. A 200-nm-thick Ti layer was sputtered on the TiCl4-treated TiO2 NW using a magnetic sputter (K575X, Quorum Technologies). The substrates were then transferred to a Teflon vessel with the addition of a 5 M aqueous NaOH solution and were encapsulated in a stainless-steel autoclave. Then, the autoclave was heated at 80 °C for 30 min. After the low-temperature hydrothermal process, the substrate was rinsed with 0.1 M HNO3 followed by deionized water, and was finally calcined at 500 °C for 30 min to obtain hierarchical nanostructures.

Figure 8. (a) Current—time curves of Au/TiO2 ARHN collected in 1 M NaOH at 0.23 V vs Ag/AgCl under 100 mW/cm2 for 3h. (b) The calculated Faradaic efficiency for O2 gas evolution. (c) Charge transfer mechanism of Au/TiO2 ARHN under solar illumination.
Synthesis of Au/TiO$_2$ ARHN. A 5-nm Au layer was sputtered on the TiO$_2$ NW and ARHN using a magnetic sputter. The Au deposited TiO$_2$ were subsequently calcined at 500°C for 1 h to obtain Au/TiO$_2$ ARHN.

Characterizations and measurements. The surface and cross-section morphologies of samples were examined by field-emission scanning electron microscopy (FE-SEM, Zeiss Ultraplus). The SigmaScan Pro 5 software was used to calculate particle size (300 particles were counted). The crystal structure was characterized by X-ray diffraction (XRD, PANalytical X’Pert Pro MRD) and Raman spectroscopy (Tokyo Instruments, INC). A UV/Vis spectrometer (Perkin Elmer/Lambda 900) was used to obtain the absorption spectra. The dye absorption/desorption experiment was performed by desorbing a dye-sensitized TiO$_2$ electrode in a 0.1 M NaOH solution in 1:1 H$_2$O/EtOH$^5$. Subsequently, a UV–vis spectrometer was introduced to measure the absorbance of the desorbing solution. The electrochemical measurement was carried out using three-electrode system. TiO$_2$ electrode with or without Au NPs was the working electrode; an Ag/AgCl (3 M KCl) electrode in saturated KCl was the reference electrode; the Pt plate was used as the counter electrode. All PEC cells were examined in 1 M NaOH solution with a PARSTAT 2263 Advanced Electrochemical System under illumination by Newport solar simulator with AM 1.5 G (100 mW/cm$^2$). The incident photon-to-current conversion efficiency (IPCE) was measured with an action spectrum measurement setup (Pecell, PEC-S20).
