Bioinformatics analysis of long non-coding RNA-associated competing endogenous RNA network in schizophrenia

Hani Sabaie1,2, Madiheh Mazaheri Moghaddam3, Marziyeh Mazaheri Moghaddam2, Noora Karim Ahangar4,5, Mohammad Reza Asadi2,4, Bashdar Mahmud Hussen6, Mohammad Taheri7* & Maryam Rezazadeh1,2*

Schizophrenia (SCZ) is a serious psychiatric condition with a 1% lifetime risk. SCZ is one of the top ten global causes of disabilities. Despite numerous attempts to understand the function of genetic factors in SCZ development, genetic components in SCZ pathophysiology remain unknown. The competing endogenous RNA (ceRNA) network has been demonstrated to be involved in the development of many kinds of diseases. The ceRNA hypothesis states that cross-talks between coding and non-coding RNAs, including long non-coding RNAs (lncRNAs), via miRNA complementary sequences known as miRNA response elements, creates a large regulatory network across the transcriptome. In the present study, we developed a lncRNA-related ceRNA network to elucidate molecular regulatory mechanisms involved in SCZ. Microarray datasets associated with brain regions (GSE53987) and lymphoblasts (LBs) derived from peripheral blood (sample set B from GSE73129) of SCZ patients and control subjects containing information about both mRNAs and lncRNAs were downloaded from the Gene Expression Omnibus database. The GSE53987 comprised 48 brain samples taken from SCZ patients (15 HPC: hippocampus, 15 BA46: Brodmann area 46, 18 STR: striatum) and 55 brain samples taken from control subjects (18 HPC, 19 BA46, 18 STR). The sample set B of GSE73129 comprised 30 LB samples (15 patients with SCZ and 15 controls). Differentially expressed mRNAs (DEmRNAs) and lncRNAs (DElncRNAs) were identified using the limma package of the R software. Using DIANA-LncBase, Human MicroRNA Disease Database (HMDD), and miRTarBase, the lncRNA-associated ceRNA network was generated. Pathway enrichment of DEmRNAs was performed using the Enrichr tool. We developed a protein–protein interaction network of DEmRNAs and identified the top five hub genes by the use of STRING and Cytoscape, respectively. Eventually, the hub genes, DElncRNAs, and predictive miRNAs were chosen to reconstruct the subceRNA networks. Our bioinformatics analysis showed that twelve key DEmRNAs, including BDNF, VEGFA, FGF2, FOS, CD44, NRAS, SPARC, ZFP36, FGG, ELAVL1, and STARD13, participate in the ceRNA network in SCZ. We also identified DLX6-AS1, NEAT1, MINCR, LINC01094, DLGAP1-AS1, BABAM2-AS1, PAX8-AS1, ZFHX4-AS1, XIST, and MALAT1 as key DElncRNAs regulating the genes mentioned above. Furthermore, expression of 15 DEmRNAs (e.g., ADM and HLA-DRB1) and one DElncRNA (XIST) were changed in both the brain and LB, suggesting that they could be regarded as candidates for future biomarker studies. The study indicated that ceRNAs could be research candidates for investigating SCZ molecular pathways.

Schizophrenia (SCZ) is a severe psychotic disorder with a lifetime risk of almost 1%. SCZ is considered one of the ten most common causes of disability throughout the world1. The symptoms of SCZ are usually classified into

1Molecular Medicine Research Center, Tabriz University of Medical Sciences, Tabriz, Iran. 2Department of Medical Genetics, Faculty of Medicine, Tabriz University of Medical Sciences, Tabriz, Iran. 3Department of Genetics and Molecular Medicine, School of Medicine, Zanjan University of Medical Sciences (ZUMS), Zanjan, Iran. 4Immunology Research Center, Tabriz University of Medical Sciences, Tabriz, Iran. 5Student Research Committee, Tabriz University of Medical Sciences, Tabriz, Iran. 6Department of Pharmacognosy, College of Pharmacy, Hawler Medical University, Kurdistan Region, Erbil, Iraq. 7Men’s Health and Reproductive Health Research Center, Shahid Beheshti University of Medical Sciences, Tehran, Iran. *email: Mohammad_823@yahoo.com; Rezazadehm@tbzmed.ac.ir
three categories: positive symptoms such as hallucinations, delusions, and thinking problems; negative symptoms such as diminished emotions, reduced motivation, decreased speaking, and social deterioration; cognitive symptoms such as attention, emphasis, processing speed, and memory dysfunctions. The etiology of SCZ is demonstrated to be multifactorial, in which both environmental and genetic factors have been identified to participate in the manifestation of symptoms. Dysregulated gene expression and protein production are considered to be associated with the pathophysiology of SCZ and have spatial variation across brain regions and temporal variation during disease progression. A recent postmortem transcriptional profiling study shows a considerable burden of differentially expressed genes (DEGs) across hippocampus (HPC), Brodmann area 46 (BA46), and striatum (STR) regions and reveals that multiple signaling and inflammatory pathways are dysregulated in all three regions in SCZ. On the other hand, a growing body of evidence has indicated that the brain is linked to the periphery via the circulatory system containing hormones and other secreted regulatory molecules produced in the diffuse neuroendocrine system which impact the gene expression pattern of the peripheral markers. These findings are confirmatory evidence that SCZ is a systemic disorder and support the notion that investigation of the SCZ can be through studying the biomarkers in the peripheral samples such as whole blood, peripheral blood mononuclear cells (PBMCs), lymphoblasts (LBs), and olfactory epithelium. Numerous studies demonstrated alterations in non-coding RNA (ncRNA) in people with SCZ. These findings provided information concerning the underlying mechanisms of dysregulation in gene expression and protein production. The ncRNA entails several RNA molecule families with a genetic distinction based on mature sequence size. A growing body of evidence suggests that microRNAs (miRNAs) (20–22 nucleotides) are aberrantly expressed in the brains of SCZ patients. Furthermore, new research indicates that the aberrant expression of other ncRNAs, including long non-coding RNAs (lncRNAs) with more than 200 nucleotides, could be implicated in SCZ.

Remarkable data have been provided about the molecular mechanisms and biological procedures of SCZ through advanced genomic, developmental neurobiology and systems biology investigations. High-throughput discovery of genes that contribute to the molecular pathology of SCZ is now possible using microarray technologies and next-generation sequencing. The role of genetic in SCZ pathophysiology is still vague, and newly discovered mechanisms responsible for regulating gene transcription could be beneficial in resolving how these alterations cause the development and progression of SCZ. As a result, potencies for more efficient treatment and diagnosis are found. Pier Paolo Pandolfi and colleagues recommended a novel regulatory mechanism, known as competing endogenous RNA (ceRNA), in 2011. It was suggested that cross-talk between both coding and non-coding RNAs such as lncRNAs, circular RNAs (circRNAs), and pseudogenes via miRNA response elements (MREs), as miRNA complementary sequences, leads to the formation of a large-scale regulatory network in diverse parts of the transcriptome. According to the ceRNA hypothesis, RNAs transcripts can regulate each other by competing for shared miRNAs. In addition, the expression levels of these two RNA transcripts will have a positive relationship with each other. Over the last few years, numerous studies have validated the ceRNA theory. It is well known that disruption of the balance of ceRNA cross-talk is associated with various developmental processes and pathological conditions, including tumorigenesis, neurodegenerative diseases (e.g., Alzheimer’s disease (AD)), and mental disorders (e.g., SCZ and depression).

Given that SCZ is one of the ten most prevalent causes of disability globally and since the nature of the genetic component in SCZ pathophysiology is not fully understood, we performed a bioinformatics analysis to elucidate the lncRNA-associated ceRNA network to clarify molecular regulatory mechanisms involved in SCZ.

**Methods**

In the present study, we employed a system biology approach to mine data of the two microarray datasets of multiple regions of the brain (GSE53987) and the LBs derived from peripheral blood (sample set B from GSE73129) from SCZ subjects with SCZ and matched controls. We intended to recognize differentially expressed mRNAs (DEmRNAs) and lncRNAs (DElncRNAs) and make a lncRNA-associated ceRNA network. All methods were carried out in accordance with relevant guidelines and regulations.

**Gene expression profile data collection.** The gene expression profiles mentioned above were obtained from the NCBI Gene Expression Omnibus database (GEO). A chip-based platform GPL570 (HG-U133_Plus_2) Affymetrix Human Genome U133 Plus 2.0 Array was applied for both datasets. The GSE53987 included 48 brain samples from SCZ patients (15 HPC, 15 BA46, 18 STR) and 55 brain samples from control subjects (18 HPC, 19 BA46, 18 STR). The sample set B from GSE73129 contained 30 LB samples, of which 15 were SCZ patients, and 15 were control.

**Data preprocessing and DEmRNAs and DElncRNAs identification.** We used Robust Multichip Average (RMA) for background correction, and quantile normalization of all the raw data files. Brain regions and LB samples were normalized separately. An interquartile range (IQR) filter (IQR across the samples on the log base two scale greater than median IQR) was used to reduce the number of evaluated genes followed by an intensity filter (a minimum of > 100 expression signals in a minimum of 25% of the arrays) aiming to remove the non-significant probe sets which are not expressed or not changing. AgiMicroRna Bioconductor package was used for assessing the quality control. We employed principal component analysis (PCA) to conduct a dimensional reduction analysis, aiming to find similarities between each sample group using R software's ggplot2 package. Besides, a heatmap was drawn to show the correlation between samples using the Hheatmap package. Differential expression gene analysis (DEGA) was done between SCZ and normal samples using the linear models for microarray data (limma) R package in Bioconductor. We used the removeBatchEffect() function from the limma package to remove batch effects. Age, gender, and race were used as covariates in GSE73129 study and race and post-mortem interval in GSE53987 study to modify
the data for confounding variables. We did a linear model on the main factor "group" (disease vs. control) using limma's lmFit() function and included covariates in the linear model as well. The limma's eBayes () function was then used to calculate differentially expressed data from the linear fit model. We utilized the previously used approach to identify IncRNA probes\(^3,4\). We downloaded the complete list of IncRNA genes with approved HUGO Gene Nomenclature Committee (HGNC) symbols from [https://www.genenames.org/]\(^5\). Then, we compared the IncRNA gene list with our dataset gene symbols and chose the overlapped genes. Student t-test was used and we set the aberrantly expressed RNAs cut-off as: (1) a false discovery rate (adjusted -value) < 0.001, and (2) |log2 fold change (log2FC)|> 0.69. Note that we discarded probes with no gene symbols.

**IncRNA-associated ceRNA network construction.** DIANA-LncBase v3\(^6\) was used to identify the experimentally validated interactions between the miRNAs and IncRNAs. Homo Sapiens "Species", Brain or Peripheral Blood "Tissue", and high "miRNA Confidence Levels" were selected as criteria for the DIANA-LncBase query. SCZ-related miRNAs were collected from the Human microRNA Disease Database (HMDD) v3.2 database\(^7\). Besides, we obtained the interactions between miRNAs that were collected using the HMDD database and target mRNAs supported by strong experimental evidence from miRTarBase\(^8\). These mRNAs were then compared with the previously obtained mRNAs. Then, we used the duplicated mRNAs to construct the IncRNA-miRNA-mRNA network. LncRNAs, targeted mRNAs, and the interacted miRNAs were removed from the ceRNA network in the opposite expression pattern between the targeted mRNAs and IncRNAs. Cytoscape software (version 3.8.0)\(^9\) was used to generate ceRNA regulatory network.

**Pathway enrichment analysis of DEmRNAs.** The Kyoto Encyclopedia of Genes and Genomes (KEGG) enrichment analysis was performed using the Enrichr tool\(^10,11\) for pathway enrichment to analyze the DEmRNAs that were in the ceRNA network.

**Protein–protein interaction (PPI) network construction and hub genes identification.** A PPI network was constructed using online STRING database [https://string-db.org/]\(^12\) for predicting the interactive relationships of common DEmRNAs encoding proteins. A minimum interaction score of above 0.7 (high confidence) was needed for PPI network construction. Cytoscape software was employed for PPI network visualization and hub genes analysis. For PPI network simplification, we removed the non-interacting genes. Then, we considered the top five genes with the highest degree of connection to the others as the hub genes according to CytoHubba (version 0.1)\(^13\) from Cytoscape.

**Reconstruction of the subceRNA network.** We retrieved the corresponding IncRNA and miRNA from the original network of ceRNA. We used them in the reconstruction of the subceRNA network to confirm the ceRNA network of hub genes.

**Results**

**DEmRNAs and DELncRNAs identification.** Background correction, normalization, gene filtration, and batch correction were performed prior to DEGA. We applied AgiMicroRna Bioconductor package for quality control assessment. Box plots of gene expression data were depicted to evaluate data distribution following normalization (Supplementary Fig. S1). In the box plots, separate arrays had similar medians of expression level, confirming that correction was carried out properly. We checked sample correlation at the probe level. The samples were divided into two main clusters, one of which had SCZ, and the other consisted of the control samples. Moreover, a PCA plot was used to demonstrate the spatial distribution of samples (Fig. 1). PCA presents information about the structure of the analyzed data. It helps find similarities between samples. One of the STR samples in the SCZ group was removed due to being spatially far from other SCZ samples. The number of DEmRNAs and DELncRNAs are listed in Supplementary Table S1. Our analysis with the limma package in R identified 249 DEmRNAs (228 upregulated and 21 downregulated) (e.g., BDNF: brain-derived neurotrophic factor, VEGFA: vascular endothelial factor A, FGF2: fibroblast growth factor 2, FOS, and CD44), eight DELncRNAs (six upregulated and two downregulated) (e.g., DLX6-AS1: DLX6 antisense RNA 1, NEAT1: nuclear-enriched abundant transcript 1, MINCR: MYC-induced long non-coding RNA, LINC01094: long intergenic non-protein coding RNA 1094, DLGAP1-AS1: DLGAP1 antisense RNA 1, BABAM2-AS1: BABAM2 antisense RNA 1, and PAX8-AS1: PAX8 antisense RNA 1) in HPC region, 286 DEmRNAs (271 upregulated and 15 downregulated) (e.g., VEGFA, FGF2, CD44, SOX2: SRY-box transcription factor 2, and Nras), five DELncRNAs (five upregulated) (including, NEAT1, MINCR, LINC01094, PAX8-AS1, and ZFHX4-AS1: ZFHX4 antisense RNA 1) in HPC region, 271 DEmRNAs (250 upregulated and 21 downregulated) (e.g., VEGFA, SPARC: secreted protein acidic and rich in cysteine, ZFP36, FGG: fibrinogen gamma chain, and ELAVL1: ELAV-like protein 1), seven DELncRNAs (six upregulated and one downregulated) (e.g., NEAT1, MINCR, LINC01094, DLGAP1-AS1, PAX8-AS1, and XIST: X-inactive specific transcript) in STR region, 159 DEmRNAs (39 upregulated and 120 downregulated) (e.g., STARD13: StAR-related lipid transfer protein 13), and two IncRNAs (two upregulated) (e.g., MALAT1: metastasis associated lung adenocarcinoma transcript 1) in LB. Among the genes mentioned above, only BDNF and DLX6-AS1 genes had decreased expression and others showed increased expression. The complete lists of DEGs are shown in Supplementary Tables S2–S5. Moreover, the Venn diagram indicated 15 DEmRNAs (ADM, CLEC2B, F13A1, HLA-DQb1, HLA-DRB1, HLA-DRB3, HLA-DRB4, HLA-DRB5, CSF2RB, RHPN2, DDX3Y, EIFIY, KDM5D, RPS4Y1, USP9Y) and one DELncRNAs (XIST) were dysregulated in both brain and LB. The details of these overlapped genes are shown in Fig. 2 and Table 1.
Figure 1. Hierarchically clustered correlation heatmap and principal component analysis (PCA) for the brain dataset (GSE53987) are shown in (a) and (b), and for the lymphoblast dataset (GSE73129) are depicted in (c) and (d), respectively. Each column in the heatmap represents one sample and shows the correlation to all samples (including itself), with red for correlation = 1 and blue for the lowest observed correlation. All SCZ and CTL samples correlated well with each other, except one SCZ sample from the GSE53987 study marked by an asterisk (*). In PCA, all samples are segregated by condition group (on PC1). GSM1305052 (a patient striatum sample) was removed from further analysis in order to its wrong spatial enrichment. This figure was made using R version 4.0.3 (https://www.r-project.org/). CTL, control; SCZ, schizophrenia.

Figure 2. Analysis of differentially expressed genes (DEGs) in Schizophrenia (SCZ) brain and lymphoblast samples by Venn. Co-expression of (a) DEmRNAs and (b) DEIncRNAs in different brain regions and lymphoblast of SCZ patients. This figure was made using R version 4.0.3 (https://www.r-project.org/). BA46, Brodmann area 46; HPC, hippocampus; LB, lymphoblast; STR, striatum.
lncRNA-associated ceRNA network construction. The DIANA-LncBase v3 online tool was used to anticipate DElncRNA-miRNA interaction pairings. DELncRNAs, targeted DEMRNAs, and also the interacted miRNAs were deleted from the ceRNA network in the opposite expression pattern present between DElncRNAs and the targeted DEMRNAs. Following that, miRTarBase was utilized to identify interactions between target mRNAs and SCZ-associated miRNAs (discovered by the HMDD). We developed a regulatory ceRNA network based on DElncRNA-miRNA-DEmRNA interactions to explore the potential mechanism behind SCZ pathophysiology (Fig. 3 and Table 2). CeRNA network contained 50 nodes (seven lncRNAs, 17 miRNAs, and 26 mRNAs) and 95 edges in HPC, 54 nodes (five lncRNAs, 19 miRNAs, and 30 mRNAs) and 101 edges in BA46, 54 nodes (seven lncRNAs, 19 miRNAs, and 28 mRNAs) and 97 edges in STR, and three nodes (one lncRNA, one miRNA, and one mRNA) and two edges in LB. There was no common ceRNA axis between LB and brain regions. We identified one ceRNA axis in LB (MALAT1/hsa-miR-9-5p/STARD13). Among the list, 90 different ceRNA axes were common between all three areas of the brain. These ceRNA axes are bolded in Table 1.

Pathway enrichment analysis of DEMRNAs. A KEGG enrichment analysis of all expressed DEMRNAs that were in the ceRNA network was conducted. The top five enriched KEGG pathways were "Kaposi sarcoma-associated herpesvirus infection", "Hepatitis B", "MAPK signaling pathway", "Relaxin signaling pathway", and "FoxO signaling pathway" (Fig. 4).

Table 1. List of DEMRNAs and DElncRNAs that were dysregulated in both brain and blood. BA46 Brodmann area 46, DElncRNA differentially expressed IncRNA, DEmRNAs differentially expressed mRNAs, HPC hippocampus, LB lymphoblast, STR striatum.
| DElncRNA(s) | Shared miRNA(s) | DEmRNA(s) | Sample | Expression of DElncRNA(s) and DEmRNA(s) |
|------------|----------------|-----------|--------|----------------------------------------|
| DLX6-AS1   | hsa-miR-22-3p  | ACVR1C, BDNF | HPC    | Down                                  |

**Figure 4.** Overall results of pathway enrichment analysis. The bar chart shows the top five enriched pathways, along with their corresponding P-values. Colored bars correspond to terms with significant P-values (< 0.05). An asterisk (*) next to a P-value indicates the term also has a significant adjusted P-value (< 0.05). This chart was generated with Appyter (https://appyters.maayanlab.cloud/#/)⁴⁴.

**PPI network construction and hub genes identification.** The PPI network of three brain regions is shown in Fig. 5a–c. We assessed their degree of connection and recognized 11 hub genes in three brain regions (BDNF, VEGFA, FGF2, FOS, CD44, SOX2, NRAS, SPARC, ZFP36, FGG, and ELAVL1), which were all upregulated except BDNF. The strongest connections with others were observed for the hub genes marked with red nodes. In addition, orange and yellow nodes represent the hub genes with moderate and weak connections, respectively (Fig. 5d–f). VEGFA had the strongest connections with others in the HPC region, FGF2 had moderate connections, while the hub genes CD44, BDNF, and FOS had weak connections. The VEGFA hub gene had the strongest connections with others in the BA46 region, whereas the hub genes CD44 and FGF2 had moderate connections, and the hub genes NRAS and SOX2 had weak connections. The VEGFA gene exhibited the strongest connections with others in the STR region, whereas the hub genes ELAVL1, SPARC, FGG, and ZFP36 had weak connections. Based on these findings, VEGFA had the strongest connections in all three regions of the brain. Two other genes (FGF2 and CD44) were also identified as hub genes in both HPC and BA46 regions.

**Reconstruction of the subceRNA network.** Based on the hub genes, the lncRNA-miRNA-hub genes’ subnetwork of three brain regions was reconstructed. In total, nine lncRNAs (DLX6-AS1, NEAT1, MINCR, LINC01094, DLGAP1-AS1, BABAM2-AS1, PAX8-AS1, ZFHX4-AS1, and XIST), 17 miRNAs (hsa-miR-124-3p, hsa-miR-132-3p, hsa-miR-15a-5p, hsa-miR-22-3p, hsa-miR-126-3p, hsa-miR-15b-5p, hsa-miR-195-5p, hsa-miR-20b-5p, hsa-miR-29a-3p, hsa-miR-29c-3p, hsa-miR-34a-5p, hsa-miR-7-5p, hsa-miR-98-5p, and hsa-miR-9-5p) and 11 hub genes (BDNF, VEGFA, FGF2, FOS, CD44, SOX2, NRAS, SPARC, ZFP36, FGG, and ELAVL1) were included (Fig. 6). We used “key lncRNAs,” “key miRNAs,” and “key mRNAs” keywords to refer to these transcripts, respectively. CeRNA axes in which the lncRNA NEAT1 regulates the VEGFA via sponging different miRNAs (e.g., miR-29 family and miR-20b), as well as MALAT1/hsa-miR-9-5p/STARD13 (the only axis identified in the LB), could be good candidates for future experimental studies in different brain regions and peripheral blood of SCZ patients, respectively.
Figure 5. Protein–protein interaction (PPI) network of differentially expressed mRNAs (DEmRNAs) and hub genes in three brain regions. Blue nodes show the interaction among DEmRNAs in the PPI network in (a) hippocampus (HPC), (b) Brodmann area 46 (BA46), and (c) striatum (STR) regions. Hub genes in (d) HPC, (e) BA46, and (f) STR regions identified from the PPI network. Red, orange, and yellow nodes represent the hub genes with strong, moderate, and weak connections, respectively. This figure was generated using Cytoscape version 3.8.0 (https://cytoscape.org/)39.

Figure 6. The lncRNA-miRNA-hub gene subceRNA network. ceRNA axes in (a) hippocampus, (b) Brodmann area 46, and (c) striatum regions. The red and blue nodes represent the upregulation and downregulation, respectively. Gray edges represent interactions between RNAs. LncRNAs, miRNAs, and mRNAs are represented by hexagon, round rectangle, and ellipse, respectively. This figure was generated using Cytoscape version 3.8.0 (https://cytoscape.org/)39. CeRNA, competing endogenous RNA.
Discussion

The expression patterns of ceRNA differ depending on tissue-related, cellular, and subcellular circumstances. A network might consist of different types of ceRNAs, such as lncRNAs, circRNAs, pseudogenes, as well as miRNAs. LncRNAs, one of the major forms of RNAs, are identified in the ceRNA machinery and perform a significant role in physiological and pathological cellular mechanisms. It has been revealed that they are implicated in a variety of mental disorders (e.g., AD, SCZ, and autism spectrum disorder (ASD)) [48]. It is now well accepted that IncRNA expression varies by tissue, cellular types, and developmental levels. This tissue specificity, besides subcellular distributions, clearly indicates that IncRNA expression is tightly regulated [49]. According to the as-mentioned theoretical concepts, the ceRNA regulation network related to IncRNAs can play a crucial role in SCZ pathogenesis. In this study, we used a public database to download the expression profiles of different types of SCZ tissues to evaluate the DElncRNAs and DEMiRNAs in SCZ and normal tissues and then create an lncRNA-miRNA-mRNA regulatory network. We identified possible lncRNA-miRNA-mRNA axes in the pathogenesis of SCZ consisting of nine key lncRNAs, 17 key miRNAs, 11 key mRNAs in the brain, and one key IncRNA, one key miRNA, one key mRNA in LB.

LncRNA expression has been hypothesized to be dysregulated in SCZ and might be involved in the pathogenesis [44]. Among the key IncRNAs identified by our analysis, only the association of NEAT1, MALAT1, and DLX6-AS1 with SCZ has been the specific focus of previous studies. NEAT1 is a member of the IncRNA family highly enriched in the mammalian brain [45]. It is a crucial scaffolding unit as well as a structural determinant of paraspeckles [46], which is a subnuclear structure implicated in several cellular processes such as splicing and transcriptional modulation through chromatin structure modification [47]. This type of lncRNA has already been found to be upregulated in other types of mental illnesses, namely Huntington’s disease [48] and ASD [49]. Studies related to the comparison of NEAT1 expression in the patients with SCZ against the control group have shown contradictory findings. Some studies identified downregulation of NEAT1 in peripheral blood [50] and multiple subareas of the cerebral cortex such as BA46 and HPC [51] of SCZ patients compared with healthy controls. However, others revealed no significant differences in peripheral blood [52] or upregulation in BA46, HPC, and STR regions [53], which is similar to our results. Further studies are needed to explain these contradictory findings. MALAT1 is predominantly expressed in nerve cells and is transcriptionally elevated in nuclear speckles. It has been reported that MALAT1 employs splicing proteins of the Ser/Arg (SR) family in transcription sites in order to regulate synaptogenesis-related gene expression in hippocampal neurons cultivated. Furthermore, in this system, knocking down MALAT1 results in a reduction in synaptic density, while overexpression promotes the density [54]. A study recently has shown no substantial variation in the expression level of MALAT1 in SCZ patients’ peripheral blood compared with healthy control [55]. This finding is inconsistent with our results which might be attributed to the treatment of the patients with clozapine. The upregulation of DLX6-AS1, a regulator of GABAergic interneuron development [56], in cerebral organoids derived from induced pluripotent stem cells showed that it might play a key role in ASD and SCZ pathogenesis [57]. In addition, we found XIST as another key IncRNA in the ceRNA network, which is associated with mental disorders. LncRNA XIST regulates the inactivation of the X chromosome, which is a critical developmental mechanism in the brain. XIST is highly expressed in lymphoblastoid cells from female patients diagnosed with bipolar disorder or recurrent severe depression as well as postmortem human brains of female psychiatric patients. Our results are in line with these findings. To our knowledge, the association of the other six key IncRNAs (MINCR, LINC01094, DLGAP1-AS1, BABAM2-AS1, PAX8-AS1, and ZFHX4-AS1) has not been the specific focus of investigations in the context of mental disorders. MINCR is a Myc-induced IncRNA related to some cancers via acting as a ceRNA [58]. Similarly, recent studies report that LINC01094 [59], DLGAP1-AS1 [60], and PAX8-AS1 [61] can act as a ceRNA in some cancers. Besides, it has been shown that BABAM2-AS1 (also known as BBE-AS1) [62] and ZFHX4-AS1 [63] regulate cancer cells through multiple mechanisms. The association between some of the IncRNAs with SCZ has been reported in this study for the first time; therefore, further studies are needed to validate our findings.

MiRNAs control target gene expression by attaching to the non-transcription site of the targeted gene, which then influences biological and signals transduction pathways in a cell, with potential effect on the onset and progression of SCZ [64]. In our work, we found that key IncRNAs may regulate hub genes via sponging 17 SCZ-associated key miRNAs (hsa-miR-124-3p, hsa-miR-132-3p, hsa-miR-15a-5p, hsa-miR-22-3p, hsa-miR-126-3p, hsa-miR-15b-5p, hsa-miR-17-5p, hsa-miR-195-5p, hsa-miR-20b-5p, hsa-miR-29a-3p, hsa-miR-29b-3p, hsa-miR-29c-3p, hsa-miR-34a-5p, hsa-miR-7-5p, hsa-miR-126-5p, hsa-miR-98-5p, and hsa-miR-9-5p). Our prediction is that most of these miRNAs show decreased expression, except for miRNAs that target hub genes that have reduced expression (e.g., BDNF). According to the HMDD database, some of these miRNAs, such as miR-132, miR-195, miR-20b, miR-29 family, are downregulated, while some others, such as miR-15 family, miR-126, miR-17 family, are upregulated in some brain regions of SCZ patients. Although most of these findings can confirm our results, the predicted ceRNA axes must still be validated by molecular techniques such as luciferase reporter systems, co-immunoprecipitation assays, and PCR.

In the present study, KEGG enrichment analysis was performed as well. The results showed that most of the DEMiRNAs involve in viral infection and three different signaling pathways. A previous study found a higher prevalence of human herpesvirus 8 (HHV8) infection in the patients with SCZ against the control group [65]. HHV8 has been associated with the development of Kaposi sarcoma [66]. Previously, a meta-analysis demonstrated that people with SCZ are more likely to have infectious hepatitis, which could be attributed to behavioral, immunological parameters, or both [67]. It is also shown that expression levels of mitogen-activated protein kinase (MAPK) and forhead box O (FOXO) pathway-related genes are altered in SCZ. Association between relaxin polymorphisms and SCZ also suggests that the relaxin pathway plays a role in the development of SCZ [68]. Dysfunction of these signaling pathways might lead to functional pathology in SCZ.
We found that 15 mRNAs (ADM, CLEC2B, F13A1, HLA-DQB1, HLA-DRB1, HLA-DRB3, HLA-DRB4, HLA-DRB5, CSF2RB, RHPN2, DDX3Y, EIF1AY, KDM5D, RPS4Y1, USP9Y) and one lncRNA (XIST) were differentially expressed in the LB and brain of patients with SCZ using a Venn diagram, suggesting that these mRNAs could be regarded as a biomarker for SCZ. Among them, ADM\(^7\) and HLA-DRB1\(^7\) have been suggested as biomarkers in previous studies.

Twelve key mRNAs (BDNF, VEGFA, FGF2, FOS, CD44, SOX2, NRAS, SPARC, ZFP36, FGG, ELAVL1, and STARD13) were reported in this study. BDNF is capable of regulating neuroplasticity, inhibiting the cascade of apoptosis, and raising the expression of many cellular proteins essential for neurogenesis, neuronal proliferation, as well as survival\(^9\). A myriad of studies have shown that low BDNF levels are associated with poor cognitive skills in SCZ patients\(^9\), which is consistent with our result. The VEGFA molecule is necessary for angiogenesis, brain plasticity, and neurogenesis, and it differs from other neurotrophic factors due to its significant angiogenic role. VEGFA can enhance the proliferation of neural stem cells, endothelial cells, mature astrocytes, and neurons. VEGF signaling is changed in SCZ, according to the results from transcriptomic, epigenomic, and genetic variation studies in hippocampus and prefrontal cortex samples\(^8\). In addition, FGF2 is involved in angiogenesis. FGF2 was later confirmed to be a neurotrophic factor, significant in neural development and central nervous system maintenance. Serum levels of FGF2 protein were found to be substantially higher in patients with first-episode, drug-free SCZ\(^4\). As one of the immediate early genes most studied in the brain, FOS is believed to play a significant role in SCZ pathophysiology. In line with our findings, FOS is upregulated in some areas of an SCZ rat model brain\(^8\). Contrarily, some research found that FOS is highly expressed in non-neural peripheral specimens in addition to the reduction of the FOS in the brain of SCZ patients\(^8\). More research is required to understand these conflicting findings. Also, contradictory results have been obtained from the study of CD44\(^4\) and SPARC\(^87\) dysregulation components of the brain extracellular matrix, in some brain regions. Another key gene in our study was SOX2. The association of this gene, which is a promoter of neurogenesis, with SCZ has been investigated in some animal studies\(^88,89\). The NRAS-encoded protein, a Ras superfamily intrinsic GTPase, is commonly associated with cancer progression and advancement. It is also essential in neurodevelopmental disorders due to its involvement in signal transduction from activated receptors toward the MAPK cascade. A previous study reported higher expression of this gene in the frontal cortex of SCZ patients\(^8\). This data is in agreement with our results. The genetic network of hemostatic procedure demonstrated that FGG, as a coagulation-related mediator gene, may have a role in SCZ\(^91\). ELAVL1 plays a crucial role in mRNA stabilization (mediated by AU-rich elements) and translation as well as neuronal mRNA post-transcriptional regulation. The capability of ELAVL1 in stabilizing mRNA targets may be influenced by posttranslational modifications. It is postulated that an inefficient regulation of MeCP2 transcription in the SZ cohort is caused by alterations in one of its interactant targets, ELAVL1\(^92\). To the best of our knowledge, the role of two other key genes (i.e., ZFP36 and STARD13) has not been investigated in SCZ thus far. Similar to ELAVL1, ZFP36 is disease-relevant RNA-binding proteins (RBPs) that interact with AU-rich sequences, but unlike ELAVL1, ZFP36 mediates the decay of target mRNAs\(^93,94\). In addition, its association with mental conditions (e.g., AD\(^7\) and suicidal behavior\(^95\)) has been reported previously. Moreover, STARD13, a GTPase-activating protein (GAP), inhibits RhoA and Cdc42 specifically in glioblastoma cells and other types of tumor models\(^96\).

There are some limitations in the present study. First, variations in methodology and the preparation of samples, the platform, patient characteristics, and data processing may all have an effect on gene expression profiles\(^77,79\). Secondly, it is challenging to explain dynamic variations in disease progression and the emergence of complications using postmortem brains\(^10\). Finally, a validation analysis is needed to substantiate the reliability of our findings.

**Conclusion**

In conclusion, this study identified an lncRNA-associated ceRNA network potentially relevant for SCZ. This network includes key mRNAs (including BDNF, VEGFA, FGF2, FOS, CD44, SOX2, NRAS, SPARC, ZFP36, FGG, ELAVL1, and STARD13), and lncRNAs (DLX6-AS1, NEAT1, MIRCR, LINCO1094, DLGAP1-AS1, BABAM2-AS1, PAX8-AS1, ZFHX4-AS1, and XIST). While the functions of this network need to be investigated, the present study provides potential research targets to study molecular mechanisms which could be relevant for the pathogenesis of SCZ.
