We point out that extensions of the Standard Model with low scale (~ TeV) lepton number violation (LNV) generally lead to a pattern of lepton flavor violation (LFV) experimentally distinguishable from the one implied by models with GUT scale LNV. As a consequence, muon LFV processes provide a powerful diagnostic tool to determine whether or not the effective neutrino mass can be deduced from the rate of neutrinoless double beta decay. We discuss the role of $\mu \to e\gamma$ and $\mu \to e$ conversion in nuclei, which will be studied with high sensitivity in forthcoming experiments.

In the past few years convincing experimental evidence for neutrino oscillations has been collected 1, implying that neutrinos are massive particles, with masses much smaller than those of other known fermions. Since the Standard Model of particle physics assumes that neutrinos are massless, the study of neutrino mass and the properties of massive neutrinos provides important clues about a more fundamental theory that goes beyond the Standard Model. Among the most urgent open questions in neutrino physics are the determination of (i) neutrino properties of massive neutrinos provides important clues about a more fundamental theory that goes beyond the Standard Model. Among the most urgent open questions in neutrino physics are the determination of (i) neutrino charge conjugation properties (Dirac or Majorana) and (ii) the absolute mass scale in the spectrum.

The study of neutrinoless double beta decay ($0\nu\beta\beta$) can help addressing these issues. For one, observation of this $\Delta L = 2$ process would establish the existence of total lepton number violation (LNV), thereby implying that neutrinos are massive Majorana particles 2. Ideally, the observation of $0\nu\beta\beta$ would also help determine the absolute scale of neutrino mass, since the total decay rate ($\Gamma_{0\nu\beta\beta}$) arising from light Majorana neutrinos is proportional to the square of the effective mass, $m_{\beta\beta}$ (defined precisely below). It has long been recognized, however, that the extraction of $m_{\beta\beta}$ from $\Gamma_{0\nu\beta\beta}$ is problematic, since LNV interactions involving heavy ($\sim$ TeV) particles can make comparably important contributions to the rate. Thus, in the absence of additional information about the mechanism responsible for $0\nu\beta\beta$, one could not unambiguously infer $m_{\beta\beta}$ from $\Gamma_{0\nu\beta\beta}$.

In this Letter, we show that experimental searches for lepton flavor violation (LFV) involving charged leptons can help to address this problem by providing a powerful “diagnostic tool” for establishing the $0\nu\beta\beta$ mechanism. Here, we focus on the Standard Model-forbidden processes $\mu \to e\gamma$ and $\mu \to e$ conversion in nuclei that will be studied with unprecedented sensitivity in the forthcoming MEG 3 and MECO 4 experiments, respectively. The relevant branching ratios are $B_{\mu \to e\gamma} = \Gamma(\mu \to e\gamma)/\Gamma_{\mu}^{(0)}$ and $B_{\mu \to e} = \Gamma_{\text{conv}}/\Gamma_{\text{cap}}$, where $\mu \to e\gamma$ is normalized to the standard muon decay rate $\Gamma_{\mu}^{(0)} = (G_F^2 m_\mu^5)/(192\pi^3)$, while $\mu \to e$ conversion is normalized to the capture rate $\Gamma_{\text{cap}}$. The new experiments will probe $B_{\mu \to e\gamma}$ and $B_{\mu \to e}$ at levels that would be sensitive to the effects of LFV induced by interactions involving TeV scale particles. Since models for the generation of Majorana neutrino masses typically also imply the existence of such interactions, studies of charged lepton LFV can also provide insight into the mechanism of $0\nu\beta\beta$.

The main discriminating quantity in our analysis is the ratio $R = B_{\mu \to e}/B_{\mu \to e\gamma}$. We find that:

1. Observation of both the LFV muon processes $\mu \to e$ and $\mu \to e\gamma$ with relative ratio $R \sim 10^{-2}$ implies, under generic conditions, that $\Gamma_{0\nu\beta\beta} \sim m_{\beta\beta}^2$.

2. On the other hand, observation of LFV muon processes with relative ratio $R \gg 10^{-2}$ could signal non-trivial LNV dynamics at the TeV scale, whose effect on $0\nu\beta\beta$ has to be analyzed on a case by case basis. Therefore, in this scenario no definite conclusion can be drawn based on LFV rates.

3. Non-observation of LFV in muon processes in forthcoming experiments would imply either that the scale of non-trivial LFV and LNV is above a few TeV, and thus $\Gamma_{0\nu\beta\beta} \sim m_{\beta\beta}^2$, or that any TeV-scale LNV is approximately flavor diagonal.

(If only one process is observed, the deduced constraint on $R$ may still be of use for our analysis.) Below, we explain the basis for the above observations and discuss the requirements on scenarios that might circumvent them.

In general, $0\nu\beta\beta$ can be generated by (i) light Majorana $\nu$ exchange (helicity flip and non-flip) or (ii) heavy particle exchange (see, e.g., 3,4), resulting from LNV dynamics at some scale above the electroweak one. The relative size of heavy ($A_H$) versus light particle ($A_L$) exchange contributions to the decay amplitude can be crudely estimated as follows 7:

$$A_L \sim G_F^2 \frac{m_{\beta\beta}}{k^2}, \quad A_H \sim G_F^2 \frac{M_W^4}{A^3}, \quad \frac{A_H}{A_L} \sim \frac{M_W^4}{A^3 m_{\beta\beta}^2},$$

where $m_{\beta\beta} = \sum U^2 i m_{\nu_i}$ is the effective Majorana mass ($U_{\mu n}$ being the light neutrino mixing matrix), $k^2 \sim (50 \text{ MeV})^2$ is the typical light neutrino virtuality, and $A$
is the heavy scale relevant to the LNV dynamics. Therefore, \( \Lambda_H/A_L \sim O(1) \) for \( m_3 \sim 0.1 - 0.5 \text{ eV} \) and \( \Lambda \sim 1 \text{ TeV} \), and thus the LNV dynamics at the TeV scale leads to similar \( 0\nu\beta\beta \) decay rate as the exchange of light Majorana neutrinos with effective mass \( m_3 \sim 0.1 - 0.5 \text{ eV} \).

By itself, the \( 0\nu\beta\beta \) lifetime measurement does not provide the means for determining the underlying mechanism. The spin-flip and non-flip exchange can be, in principle, distinguished by the measurement of the single-electron spectra or polarization (see e.g. [8]). In most cases, however, the observation of the emitted electrons does not distinguish between light Majorana or heavy particle exchange. Thus, one must look for phenomenological consequences of the different mechanisms other than observables directly associated with \( 0\nu\beta\beta \). Here we point out the link between \( 0\nu\beta\beta \) mechanisms and muon LFV processes.

It is useful to formulate the problem in terms of effective low energy interactions obtained after integrating out the heavy degrees of freedom that induce LNV and effective low energy interactions obtained after integrating LFV processes. Relevant quantities in this context are the LFV scales, which in general may be distinct. As long as both scales are well above the weak scale, then \( \Gamma_{0\nu\beta\beta} \sim m_3^2 \), and one does not expect to observe LFV signals in forthcoming experiments (item 3 above). In scenarios with high scale LNV (but possibly low scale LFV), such as SUSY-GUT [9] or SUSY see-saw [10], one expects again \( \Gamma_{0\nu\beta\beta} \sim m_3^2 \), as well as \( \mathcal{R} \sim 10^{-2} \) (item 1). The case where the scales of LNV and LFV are both relatively low (\( \lesssim \text{ TeV} \)) is more subtle, as this scenario might lead to observable LFV at the same time to ambiguities in interpreting a positive signal in \( 0\nu\beta\beta \). Here one needs to develop some discriminating criteria, as we discuss in detail below.

Denoting the new physics scale by \( \Lambda \), the effective lagrangian for \( 0\nu\beta\beta \) has the form

\[
\mathcal{L}_{0\nu\beta\beta} = \sum_i \frac{c_i}{\Lambda^2} \tilde{O}_i, \quad \tilde{O}_i = q\Gamma_1 q \bar{q}\Gamma_2 e\Gamma_3 c e, \tag{2}
\]

where we have suppressed the flavor and Dirac structures for simplicity (a complete list of the dimension nine operators \( O_i \) can be found in Ref. [8]). For the LFV interactions, one has

\[
\mathcal{L}_{\text{LFV}} = \sum_i \frac{c_i}{\Lambda^2} O_i, \tag{3}
\]

and a complete operator basis can be found in Refs. [11, 12]. The LFV operators relevant to our analysis are of the following type

\[
O_{\sigma L} = \left( \frac{e}{(4\pi)^2} \right) \tilde{\ell}_i L \sigma_{\mu\nu} \tilde{\ell}_j L F^{\mu\nu} + \text{h.c.},
\]

\[
O_{\ell L} = \tilde{\ell}_i L \epsilon_{iL} \tilde{e}_L \epsilon_{jL} \ell_{mL},
\]

\[
O_{\ell q} = \tilde{\ell}_i \Gamma_1 \ell_j \tilde{q} L \bar{q}, \tag{4}
\]

along with their corresponding chiral analogues \( (L \leftrightarrow R) \). Since operators of the type \( O_{\ell} \) typically arise at the one-loop level, we explicitly display the loop factor \( 1/(4\pi)^2 \). On the other hand, in a large class of models, operators of the type \( O_{\ell} \) or \( O_{\ell q} \) may arise from both tree level exchange of heavy particles as well as loop effects. With the above choices, the leading contributions to the various \( c_i \) are nominally of the same size, typically the product of two Yukawa-like couplings or gauge couplings (times flavor mixing matrices).

In terms of these operator definitions, the ratio \( \mathcal{R} \) can be written schematically as follows (neglecting flavor indices in the effective couplings and the term with \( L \leftrightarrow R \))

\[
\mathcal{R} = \frac{\Phi_{12}}{48\pi^2} \left[ \eta_1 e^2 c_{\sigma L} + e^2 (\eta_2 c_{\ell L} + \eta_3 c_{\bar{e} q}) \log \frac{\Lambda^2}{m_\mu^2} + \eta_4 (4\pi)^2 c_{\ell q} + \ldots \right]^2 / \left[ e^2 (|c_{\sigma L}|^2 + |c_{\sigma R}|^2) \right]. \tag{5}
\]

Here, \( \eta_{1,2,3,4} \) are numerical factors of \( O(1) \), while the overall factor \( \Phi/48\pi^2 \) arises from phase space and overlap integrals involving electron and muon wave-functions in the nuclear field. For light nuclei \( \Phi = (ZF^2_p)/(g^2_V + 3g^2_A) \sim O(1) \), where \( g_{V,A} \) are the vector and axial nucleon form factors at zero momentum transfer, while \( F_p \) is the nuclear form factor at \( q^2 = -m_e^2 \) [12]. The dots indicate sub-leading terms, not relevant for our discussion, such as loop-induced contributions to \( c_{\ell q} \) and \( c_{\tilde{e} q} \) that are analytic in external masses and momenta. In contrast the logarithmically-enhanced loop contribution given by the second term in the numerator of \( \mathcal{R} \) plays an essential role. This term arises whenever the operators \( O_{\sigma L,R} \) and \( O_{\ell q} \) appear at tree-level in the effective theory and generate one-loop renormalization of \( O_{\ell q} \) (see Fig. 1).

![FIG. 1: Loop contributions to \( \mu \rightarrow e \) conversion through insertion of operators \( O_{\ell} \) or \( O_{\ell q} \), generating the large logarithm.](image)

The ingredients in Eq. (5) lead to several observations: (i) In absence of tree-level \( c_{\ell L} \) and \( c_{\bar{e} q} \), one obtains \( \mathcal{R} \sim \Phi^2/48\pi^2 \sim 10^{-3} - 10^{-2} \), due to gauge coupling and phase space suppression. (ii) When present, the logarithmically enhanced contributions compensate for the gauge coupling and phase space suppression, leading to \( \mathcal{R} \sim O(1) \). (iii) If present, the tree-level coupling \( c_{\ell q} \) dominates the \( \mu \rightarrow e \) rate leading to \( \mathcal{R} \gg 1 \).

In light of these observations, the logic underlying items 1 and 2 can be phrased as follows. In models with
TeV scale $|\Delta L| = 1,2$ interactions and generic flavor content of the couplings one finds $\tilde{c}_i/g^2 \sim c_{LL}, c_{ER}, c_{EQ}$ ($g$ is a generic gauge coupling), and thus a short-distance contribution to $0\nu\beta\beta$ is accompanied by $R \gg 10^{-2}$. We now illustrate this statement in two explicit cases: the minimal supersymmetric standard model (MSSM) with R-parity violation (RPV-SUSY) and the Left-Right Symmetric Model (LRSM).

**RPV SUSY** — If one does not impose R-parity conservation [$R = (-1)^{3(B-L)+2s}$], the MSSM superpotential includes, in addition to the standard Yukawa terms, lepton and baryon number violating interactions, compactly written as (see e.g. [13])

$$W_{RPV} = \lambda_{ijk} L_i L_j E_k^c + \lambda'_{ijk} L_i Q_j D_k^c + \lambda''_{ijk} U_i^c D_j^c H_k^c + \mu'_i L_i H_u,$$

where $L$ and $Q$ represent lepton and quark doublet superfields, while $E^c, U^c, D^c$ are lepton and quark singlet superfields. The simultaneous presence of $\lambda'$ and $\lambda''$ couplings would lead to an unacceptably large proton decay rate (for SUSY mass scale $\Lambda_{SUSY} \sim$ TeV), so we focus on the case of $\lambda'' = 0$ and set $\mu' = 0$ without loss of generality [13]. In this case, lepton number is violated by the remaining terms in $W_{RPV}$, leading to short distance contributions to $0\nu\beta\beta$, with typical coefficients [cf. Eq. (2)]

$$\frac{c_i}{\Lambda^2} \sim \frac{\lambda_{111} \lambda'^{21}_1}{m_{\tilde{z}_1}^2}, \frac{\lambda''_i \lambda_{111}}{m_{\tilde{c}_i}^2},$$

where $\alpha_s, \alpha_2$ represent the strong and weak gauge coupling constants, respectively. The RPV interactions also lead to lepton number conserving but lepton flavor violating operators [e.g. Fig. 2(b)], with coefficients [cf. Eq. (3)]

$$\frac{c_i}{\Lambda^2} \sim \frac{\lambda_{111} \lambda'_{21}}{m_{\tilde{z}_1}^2}, \frac{\lambda''_i \lambda_{111} \lambda_{112}}{m_{\tilde{c}_i}^2},$$

where the flavor combinations contributing to $c_i$ can be found in Ref. [14]. Hence, for generic flavor structure of the couplings $\lambda$ and $\lambda'$, the underlying LNV dynamics generate both short distance contributions to $0\nu\beta\beta$ and LFV contributions that lead to $R \gg 10^{-2}$.

Existing limits on rare processes strongly constrain combinations of RPV couplings, assuming $\Lambda_{SUSY}$ is between a few hundred GeV and $\sim 1$ TeV. Non-observation of LFV at future experiments MEG and MECO could be attributed either to a larger $\Lambda_{SUSY}$ (> few TeV) or to suppression of couplings that involve mixing among first and second generations. In the former scenario, the short distance contribution to $0\nu\beta\beta$ does not compete with the long distance one [see Eq. (1)], so that $\Gamma_{0\nu\beta\beta} \sim m^2_{\tilde{\nu}_e}$. On the other hand, if the $\lambda$ and $\lambda'$ matrices are nearly flavor diagonal, the exchange of superpartners may still make non-negligible contributions to $0\nu\beta\beta$.

**LRSM** — The LRSM provides a natural scenario for introducing non-sterile, right-handed neutrinos and Majorana masses [13]. The corresponding electroweak gauge group $SU(2)_L \times SU(2)_R \times U(1)_{B-L}$, breaks down to $SU(2)_L \times U(1)_{Y}$ at the scale $\Delta \gtrsim O$(TeV). The symmetry breaking is implemented through an extended Higgs sector, containing a bi-doublet $\tilde{H}$ and two triplets $\Delta_{L,R}$, whose leptonic couplings generate both Majorana neutrino masses and LFV involving charged leptons:

$$L_{LFV}^{\text{hpt}} = \frac{1}{(L_{-1}^{(i)} \Phi + \tilde{y}_D^{ij} \tilde{\Phi}) L_R^j}{(\tilde{L}_{-1}^{(i)} \tilde{\Phi} - (\tilde{L}_{-1}^{(i)} \tilde{\Phi})) y_{L}^{ij} \tilde{\Delta}_{L} L_{L}^{j} - (\tilde{L}_{-1}^{(i)} \tilde{\Phi}) y_{L}^{ij} \tilde{\Delta}_{R} L_{R}^{j}.$$

Here $\tilde{\Phi} = \sigma_2 \Phi \sigma_2, \tilde{\Delta}_{L,R} = i\sigma_2 \Delta_{L,R}$, and leptons belong to two isospin doublets $L_{L,R} = (\nu^e_{L,R}, e^+_L)$. The gauge symmetry is broken through the VEVs $\langle \Delta_{R}^{0} \rangle = v_R$, $\langle \Delta_{L}^{0} \rangle = 0$, $\langle \tilde{\Phi} \rangle = \text{diag}(\kappa_1, \kappa_2)$. After diagonalization of the lepton mass matrices, LFV arises from both non-diagonal gauge interactions and the Higgs Yukawa couplings. In particular, the $\Delta_{L,R}$-lepton interactions are not suppressed by lepton masses and have the structure $\mathcal{L} \sim \Delta_{L,R}^{ij} E_{L}^{j} h_{ij} (1 \pm \gamma_5) \chi_{L} + \text{h.c.}$. The couplings $h_{ij}$ are in general non-diagonal and related to the heavy neutrino mixing matrix [16].

Short distance contributions to $0\nu\beta\beta$ arise from the exchange of both heavy $\nu$s and $\Delta_{L,R}$ (Fig. 3), with

$$\frac{c_i}{\Lambda^2} \sim \frac{g^2}{M_{W_R}^{\pm}} \frac{1}{M_{W_R}}, \frac{g^2}{M_{W_R}^{\pm}} \frac{h_{ee}}{M_{\Delta}},$$

where $g_2$ is the weak gauge coupling. LFV operators are also generated through non-diagonal gauge and Higgs...
sort out the mechanism for a non-zero signal in $0\nu\beta\beta$ one would need additional phenomenological handles to be below the reach of up-coming LFV searches, and this work was supported in part by the Institute for Nuclear Theory, U.S. DOE contracts # DE-FG03-88ER40397 and # DE-FG02-00ER41132, and NSF Award PHY-0071856. V.C. was supported by a Sherman Fairchild Fellowship from Caltech.

Note that the Yukawa interactions needed for the Majorana neutrino mass necessarily imply the presence of LNV and LFV couplings $h_{ij}$ and the corresponding LFV operator coefficients $c_{ij}$, leading to $R \sim O(1)$. Again, non-observation of LFV in the next generation of experiments would typically push $\Delta$ into the multi-TeV range, thus implying a negligible short distance contribution to $0\nu\beta\beta$. As with RPV-SUSY, this conclusion can be evaded by assuming a specific flavor structure, namely $y_{i\ell}$ approximately diagonal or a nearly degenerate heavy neutrino spectrum.

In both of the foregoing phenomenologically viable models incorporating LNV and LFV at low scale ($\sim$ TeV), one finds $R \gg 10^{-2}$ [11, 14, 16]. We stress that the basic mechanism at work in these illustrative cases is likely to be generic: low scale LNV interactions ($\Delta L = \pm 1$ and/or $\Delta L = \pm 2$), which in general contribute to $0\nu\beta\beta$, also generate sizable contributions to $\mu \rightarrow e$ conversion, thus enhancing this process over $\mu \rightarrow e\gamma$. Barring accidental cancellations or explicit fine-tuning of flavor structures, this enhancement happens essentially through tree-level generation of four-fermion operators of the type $O_{eq}$ or $O_{\ell\ell}$.

It is possible, of course, that any short-distance LNV sufficiently strong to affect the interpretation of $\Gamma_{0\nu\beta\beta}$ is also (approximately) flavor diagonal. In this case, one would expect both branching ratios $B_{\mu \rightarrow e\gamma}$ and $B_{\mu \rightarrow e\tau}$ to be below the reach of up-coming LFV searches, and one would need additional phenomenological handles to sort out the mechanism for a non-zero signal in $0\nu\beta\beta$. Although seemingly un-natural, such a situation is not precluded theoretically. Indeed, analogous flavor fine-tuning in lepton number conserving models – such as the soft sector of the MSSM – is not unheard of, and the phenomenological absence of flavor changing neutral currents presents a challenge to model builders to explain why a given theory is flavor diagonal when a richer flavor structure is generically available. Were a similar situation to arise in the presence of low-scale LNV, the theoretical challenge would become all the more interesting. In this context, null results for both LFV searches would provide important experimental input.

In conclusion, we have argued that the ratio $R = B_{\mu \rightarrow e\gamma} / B_{\mu \rightarrow e\gamma}$ of muon LFV processes will provide important insight about the mechanism of neutrinoless double beta decay and the use of this process to determine the absolute scale of neutrino mass. Assuming observation of LFV processes in forthcoming experiments, if $R \sim 10^{-2}$ the mechanism of $0\nu\beta\beta$ is light Majorana neutrino exchange; if $R \gg 10^{-2}$, there might be TeV scale LNV dynamics, and no definite conclusion on the mechanism of $0\nu\beta\beta$ can be drawn based only on LFV processes.
