Abstract

Active systems, or active matter, are self-driven systems which live, or function, far from equilibrium – a paradigmatic example which we focus on here is provided by a suspension of self-motile particles. Active systems are far from equilibrium because their microscopic constituents constantly consume energy from the environment in order to do work, for instance to propel themselves. The nonequilibrium nature of active matter leads to a variety of non-trivial intriguing phenomena. An important one which has recently been the subject of intense interest among biological and soft matter physicists is that of the so-called "motility-induced phase separation", whereby self-propelled particles accumulate into clusters in the absence of any explicit attractive interactions between them. Here we review the physics of motility-induced phase separation, and discuss this phenomenon within the framework of the classic physics of phase separation and coarsening. We also discuss cases where the coarsening may be arrested, either in theories for bacterial colonies or in experiments. Most of this work will focus on the case of run-and-tumble and active Brownian particles in the absence of solvent-mediated hydrodynamic interactions – we will briefly discuss at the end their role, which is not currently fully understood in this context.

Keywords: active matter, phase separation

1. Introduction

Active systems are self-driven systems which live, or function, far from thermodynamic equilibrium. A paradigmatic example is provided by a suspension of interacting self-motile particles in equilibrium with a thermal bath at temperature $T$. This system, like active matter in general, is characterized by the

continuous partial conversion of internal energy into work [1, 2], which drives it far from equilibrium even in steady state [3].

Nature offers many examples of active matter, at very different scales: these range, for instance, from the cytoskeleton of eukaryotic cells, to whole bacterial colonies and algae suspensions, and even to bird flocks and schools [4, 5, 6, 7, 8, 9, 10, 11]. Self-propelled units can also be artificially realized in the lab in many different ways, for example by anisotropic surface treatment of colloidal particles [12, 13, 14, 15, 16, 17, 18].

The inherently nonequilibrium nature of active matter endows it with a number of non-trivial features that have no analogue in passive, equilibrium materials, such as a suspension of Brownian colloidal particles. For example, bacterial swimmers may accumulate near walls due to activity alone [19, 20], and their large scale diffusive motion may be rectified by using funnels or other asymmetric geometrical obstacles [21, 22]. Within a bacterial suspension, it is also well known both that there are violations of the fluctuation-dissipation theorem [23], and that the diffusion of passive tracers is dramatically affected by the presence of active swimmers [24, 18, 25, 26, 27, 28, 29]. The existence of a parameter to be interpreted as an effective temperature [30] for active matter has been analysed in [31, 32, 33, 18, 34]. The interplay between activity and the rodlike shape of bacteria and most other active particles leads to further surprising phenomena, such as the large scale coherent turbulent-like motion observed in bacterial monolayers [35, 24, 36, 37, 38, 39, 40], or the strikingly non-Newtonian rheology found in simulations of model active gels [41, 42, 43, 44, 45].

Our main focus in this review is another example of a phenomenon that is unique to active systems, the so-called “motility-induced phase separation”, which has attracted a lot of attention recently [46, 47, 48, 49, 50, 51, 52, 53, 54]. This term refers to the phase separation into a concentrated and a gas-like dilute phase observed in a system of self-propelled particles interacting solely via steric repulsion, when the overall density is large enough. The physics of motility-induced phase separation (henceforth MIPS) can be understood as follows. Imagine that due to a fluctuation the local density of self-propelled particle increases in some part of the system. The particles in that region will therefore slow down due to the enhanced crowding. Now, as we will understand more formally in Section 2, self-motile particles (such as bacteria) accumulate where they move more slowly, much as pedestrians in a busy street (and very much unlike colloidal particle undergoing Brownian motion). This potentially triggers a positive feedback loop, whereby particles accumulate where they are slower, further slow down due to the crowding, then accumulate even more etc. The theory which we present in Section 2, and which is fully confirmed by Brownian dynamics simulations of self-propelled spherical particles (discussed in Section 3), predicts that these clusters should coarsen so as to lead to complete phase separation. Indeed, the theory suggests that this nonequilibrium phase separation should be very similar (in the same universality class) to the phase separation in a system of passive colloidal particles which are subject to a mutual attractive interaction – according to this view the main role of activity is to provide an effective attraction
between particles, in the absence of any thermodynamic attractive force. Indeed the macroscopic description of MIPS is very similar to a Cahn-Hilliard equation for a phase separating binary fluid, albeit with some subtle important differences.

Recently, experiments have also been reported where MIPS was observed in suspensions of self-motile particles only subject to steric interactions [55]. Clustering of self-propelled synthetic particles was also found in Ref. [56, 57, 58], although in both those cases the coarsening appeared to arrest, for reasons which are still not fully understood. In particular, it is not clear to date to what extent the theory of MIPS (as discussed above and in Section 2) applies to the work of Ref. [56, 57, 58], or how to modify it in an experimentally relevant way so as to lead to microphase separation, or arrested coarsening.

Another important aspect of MIPS worth discussing is that the theory normally considers spherical self-propelled particles, whereas in most cases active particles are in practice elongated (think for instance of bacteria or chemically powered nanorods). It is therefore of interest how MIPS appears in a suspensions of rodlike, or elongated, rather than spherical, microswimmers. While several simulations of rodlike active particle exists [59, 60, 61], it is only recently that the effect of particle shape on MIPS has been directly addressed – for instance with simulations of dumbbells [52]. We will review these works in Section 3. Section 3 also contains a brief description of coarse grained theories for self-propelled particles which align locally (for instance due to steric interactions if they are rodlike in shape); such theories are more complicated that the Cahn-Hilliard-like equation governing the evolution of active spherical particles because they need to follow the dynamics of the polarisation field as well.

Finally, we will consider other ways in which MIPS can be extended in Section 4. First, we will discuss an intriguing and generic way to arrest phase separation, by coupling the motility-induced feedback described above to a logistic law for the population of active particles, used as a simple metaphor for bacterial reproduction [62]. The arrested patterns predicted by the resulting theory closely resemble those found experimentally in growing bacterial colonies within semi-solid media such as agarose gel, which are normally explained instead by bacterial chemotaxis [63]. Second, all theories discussed so far neglect solvent-mediated hydrodynamic interactions between active particles. However, in a nonequilibrium active suspension, hydrodynamic can potentially modify the steady state attained by the system, and not only its transient dynamics. Furthermore, unlike active particles in Brownian simulations, neutrally buoyant hydrodynamic swimmers in a solvent need to be force free, so that the minimal active contribution is a force dipole [3]. In Section 4.2 we will briefly review some of the studies which have appeared in the literature for suspensions of spherical squirmers [64, 65, 66, 67], where the activity arises through a non-zero imposed slip velocity at their boundary. The consequence of solvent-mediated hydrodynamics for MIPS is currently unclear, and some conflicting conclusions have been reached in the literature, possibly reflecting the dependence on details of near field interactions.
2. The physics of motility: self-trapping of self-propelled particles

In this Section we provide a simple theoretical framework to understand the theory of MIPS, or self-trapping of self-propelled particles \[7, 46, 50, 21\]. In particular, we will describe this phenomenon in terms of an instability appearing in the coarse-grained “hydrodynamic” equation manifested by the presence of a negative diffusion coefficient. To establish a hydrodynamic equation for the self-propelled swimmers, we use here a kinetic approach; similar calculations have been also presented in Ref. \[10\] and are an adaptation of Refs. \[68, 69\].

2.1. A coarse-grained theory of motility-induced phase separation

Let us consider a population of swimmers that runs for a time \(\tau\) with velocity \(v\) between two successive tumbles. Let \(f(x, u, t)\) be the distribution of active particles with position \(x\), swimming in the direction \(u\) at the time \(t\). The kinetic (Boltzmann-like) equation for the evolution of \(f\) in \(d\) dimensions can be written as

\[
\partial_t f(x, u, t) = -\nabla_x \cdot [vu f(x, u, t)] - \frac{f(x, u, t)}{\tau} + \frac{\int f(x, u, t) d^{d-1}u}{\tau \int d^{d-1}u},
\]

(2.1)

The first term on the right hand side of the equation is a convective term, where \(vu\) is the velocity; the second term is a linear term accounting for the particle that "tumble out" of \(u\), with a rate \(1/\tau\); the same rate appears in the third term, that accounts for the particles "tumbling into" the direction \(u\). The integral of \(f\) appearing in the third term is the zero-th order moment of \(f\) with respect to the orientation \(u\), which is nothing but the density \(\rho\) of swimmers in \(x\). Finally, \(\Omega_d\) denotes the \(d\)-dimensional solid angle.

A way to analyze Eq. (2.1) is to consider the so-called hydrodynamic limit in which suitable moments of the distribution functions, which are linked to macroscopic observables, change smoothly in space and in time. The idea is to perform a gradient expansion (which is very similar to the so-called Chapman-Enskog expansion \[70\]) of Eq. (2.1), which assumes that successive derivatives (gradients) are smaller and smaller on macroscopic (coarse grained scales). The distribution functions is then written as

\[
f = f^{(0)} + f^{(1)} + f^{(2)} + \ldots
\]

(2.2)

where \(f^{(n)}\) is a contribution which is \(\sim \mathcal{O}(D^n)\), where \(D\) denotes derivatives over space or time. We assume that in the hydrodynamic limit every successive derivative applied to \(f\) makes it much smaller, that is:

\[
\mathcal{O}(D^n) \ll \mathcal{O}(D^{n-1}) \ll \ldots \ll \mathcal{O}(D^1) \ll \mathcal{O}(D^0) \equiv I,
\]

hence

\[
f^{(n)} \ll f^{(n-1)} \ll \ldots \ll f^{(1)} \ll f^{(0)},
\]

(2.3)
Then, we can set up a hierarchy of equations at various orders in \( D \), by equating terms of order \( D^n \) in the left and right hand side of Eq. (2.1), as follows:

\[
\mathcal{O}(D^0) : \quad f^{(0)} = \frac{\rho}{\Omega_d} \quad (2.4)
\]

\[
\mathcal{O}(D^1) : \quad \partial_t f^{(0)} + \nabla_x (v u f^{(0)}) = -\frac{f^{(1)}}{\tau} \quad (2.5)
\]

\[
\mathcal{O}(D^2) : \quad \partial_t f^{(1)} + \nabla_x (v u f^{(1)}) = -\frac{f^{(2)}}{\tau} \quad (2.6)
\]

From Eq. (2.4) we find that no term other than \( f^{(0)} \) contributes to the coarse-grained hydrodynamic density \( \rho \). Then, by summing Eqs. (2.5) and (2.6), and taking the integral over the directions we get

\[
\partial_t \rho + \frac{1}{\Omega_d} \int \partial_\beta (v u_\beta \rho) \, d^{d-1}u + \frac{\tau}{\Omega_d} \int \partial_\alpha (v u_\alpha \rho) \, d^{d-1}u = 0, \quad (2.7)
\]

where the relations \( \int f^{(1)}(x, u, t) d^{d-1}u = \int f^{(2)}(x, u, t) d^{d-1}u = 0 \) have been used (Greek indices denote Cartesian components, and the usual convention of summation over repeated indices is implied). Then we can use the expressions of \( f^{(0)} \) from Eq. (2.4) and \( f^{(1)} \) from Eq. (2.5) in order to obtain

\[
\partial_t \rho + \int \partial_\beta (v u_\beta \rho) \, d^{d-1}u - \frac{\tau}{\Omega_d} \int \partial_\alpha (v u_\alpha \rho) \, d^{d-1}u
\]

\[
- \frac{\tau}{\Omega_d} \int \partial_\alpha (v u_\alpha \partial_\beta (v u_\beta \rho)) \, d^{d-1}u = 0. \quad (2.8)
\]

The second and the third integral in the above expression are zero by symmetry so that, using

\[
\int \frac{u_\alpha u_\beta \, d^{d-1}u}{\Omega_d} = \frac{\delta_{\alpha\beta}}{d}, \quad (2.9)
\]

we are left with

\[
\partial_t \rho = \frac{\tau}{d} \nabla \cdot [v \nabla (\rho v)]. \quad (2.10)
\]

Eq. (2.10) is at the basis of the physics of self-trapping, and has some remarkable consequences. The important point here is that the running velocity can depend on the position, that is \( v = v(x) \). In steady state conditions, the distribution (obtained by setting \( \partial_t \rho = 0 \)), is \( \rho = 1/v(x) \) – hence bacteria, or self-propelled particles, accumulate where they go slower. This may seem intuitive, but is an important property which has no counterpart in passive suspensions of Brownian particles. Indeed, consider a system of non-interacting Brownian particles, which have a position dependent diffusivity, \( D(x) \). Because the system is passive, in equilibrium the probability distribution (hence the density) needs to be proportional to the Boltzmann weight, and this would give a uniform density.
in absence of any interaction. Mathematically, this is because the correct coarse
grained equation for the density of colloidal particles $\rho(x)$ would be

$$\partial_t \rho = \nabla \cdot [D(x) \nabla \rho], \quad (2.11)$$

i.e. the diffusion and the velocity enter in different positions with respect to the
gradients! As a result, in steady state the only possible solution is $\rho$ equal to a
constant, at variance with the case of the self-propelled particles.

It turns out that this seemingly technical difference leads to dramatic dif-
ferences in the physics of motile and Brownian systems. Consider for instance
the case of a concentrated suspension of active particles, where the swim speed
decreases for density, for example, simply due to crowding. Let us consider for
simplicity an exponential decay with density,

$$v \sim e^{-\lambda \rho/2} v_0, \quad (2.12)$$

where $\lambda$ measures how steep is the decay of the swim speed with $\rho$. Eq. (2.10)
in 1D then becomes:

$$\partial_t \rho = \partial_x \left[ \tau v^2 \left( 1 - \frac{\lambda \rho}{2} \right) \partial_x \rho \right] = \partial_x \left[ D_{eff}(\rho) \partial_x \rho \right]. \quad (2.13)$$

The effective diffusion coefficient $D_{eff}$ is now a function of the density. More
importantly, for $\rho$ high enough $D_{eff} < 0$, so the effective diffusivity becomes
negative! Negative diffusion means that an infinitesimally small fluctuation leads
to a divergent increase in the density field. In other words, the system phase
separates. A regularised version of Eq. (2.13) can be written down by introducing
a fourth-order derivative, as follows,

$$\partial_t \rho = \partial_x \left[ D_{eff}(\rho) \partial_x \rho \right] - k \partial^4_x \rho \quad (2.14)$$

The latter term can be related to the surface tension between the two domains
obtained after the phase segregation: one rich in swimmers running with small
velocities; another depleted in swimmers, where their average velocity is high.

Physically, the phase separation described by Eq. (2.14) can be understood
as due to a positive feedback mechanism, which works as follows. Imagine that,
due to some small density fluctuation, there is a region where swimmers are more
concentrated. In this region, their swim speed will decrease (due to our choice of
$v(\rho)$). Now, due to the fact that the swimmers accumulate where they go slower,
the local density will increase yet more, leading to more decrease in velocity and
eventually to phase separation (in reality this happens for a sufficiently steep
decrease of swim speed with density, as predicted by Eqs. (2.13,2.14)). This
mechanism has been named “self-trapping”, and the phase separation itself is
sometimes called activity-induced, or motility-induced, phase separation [7, 46].

Eq. (2.10) and Eq. (2.14) have been derived for run-and-tumble particles, such
as bacteria; another important class of self-propelled colloids is that of “active
Brownian particles” (henceforth ABPs). In ABPs, the direction of swimming
only changes gradually, by rotational diffusion (as opposed as to “instantaneous”
tumbles) – indeed the term Brownian comes from the fact that the typical origin of the gradual change of swimming direction is rotational diffusion. Like run-and-tumble particles, ABPs also exhibit motility-induced phase separation (see Section 3, and, for instance, the theory and simulations in [46, 29]). It is important to note here that the same theory leading to Eq. (2.10) and Eq. (2.14) can be modified in a rather straightforward way to apply to ABPs, essentially by substituting $1/\tau$ with $(d - 1)D_R$ [46, 69] ($D_R$ is the rotational diffusion coefficient).

2.2. Relation with Cahn-Hilliard equation, noise and interfacial terms

The approach adopted so far neglects hydrodynamic noise, and it further lacks a systematic derivation of the $-k\partial^4_x \rho$ term, or indeed of any interfacial terms, which should be of fourth-order in gradients.

Here we briefly sketch the theory, initially derived in Ref. [46, 69] and afterwards generalized in Ref. [50, 71], in which these aspects have been included.

First, we note that Eq. (2.10) can also be written formally as a Cahn-Hilliard equation,

$$\partial_t \rho = -\nabla \cdot \left[-M(\rho) \nabla \mu\right]. \quad (2.15)$$

In Eq. (2.15), the chemical potential $\mu$ can be obtained from the functional differentiation of an effective free energy $F$ with respect to $\rho$, with $F = \int f_0 d\mathbf{r}$, and with $f_0 = \rho(\ln \rho - 1) + \int_0^\rho \ln[\bar{v}(\rho')] d\rho'$ (this was first noted in [46]). The term $M(\rho)$ is an effective mobility, equal to $\bar{v}_r^2 \rho \tau$ for run-and-tumble particles (recall from Section 2.1 that $\tau$ is the run duration, equivalently the inverse tumbling rate). An explicit calculation of the chemical potential as $\mu = \delta F/\delta \rho$ and a bit of algebra show that Eq. (2.15) is the same as Eq. (2.10).

Within the effective Cahn-Hilliard description in Eq. (2.15), the role of fluctuations can be included by added a conserved noise as follows (see [46] for details),

$$\partial_t \rho = -\nabla \cdot \left[-M(\rho) \nabla \mu + \sqrt{2M(\rho)} \Lambda\right]. \quad (2.16)$$

On the right hand side of the equation $\Lambda$ is a noise vector with components $\langle \Lambda_i(r, t) \Lambda_j(r', t') \rangle = \delta_{ij} \delta(r - r') \delta(t - t')$.

Importantly, a full analysis of the phase separation kinetics requires the presence of interface-like terms to stabilise domain walls between the two phases. This is achieved by assuming that $\bar{v}$ is not strictly local but $\bar{v} = \bar{v}(\bar{\rho})$, with $\bar{\rho}(r) = \rho + \gamma^2 \nabla^2 \rho$. This is the leading order correction allowed by rotational invariance [50]. Here $\gamma$ is a smoothing length proportional to the run length for run-and-tumble particles, or to the persistence length of ABPs: in formulas one expects $\gamma(\rho) = \gamma_0 \tau_v(\rho)$, where $\gamma_0$ is of order unity and $\tau_v$ is the orientational relaxation time (equal to either $\tau$ or to $D_R^{-1}$). This assumption relies on the fact that a single ABP samples the density $\rho$ over a length scale much greater than the interparticle spacing and is proportional to the persistence length $l(\rho) = \tau_v(\rho)/(d - 1)$. 
By using the nonlocal form of \( v(\rho) = v(\hat{\rho}) \) just advocated, it can be shown that the chemical potential including interfacial terms may be written in the following form \[50\]

\[
\mu = \ln \rho + \ln v(\rho) - \kappa(\rho)\nabla^2 \rho + O(\nabla^4 \rho),
\]

(2.17)

where \( \kappa(\rho) = -\left[\frac{\gamma_0 \tau_c}{(d-1)}\right]^2 v(\rho) \frac{dv}{d\rho} \). It is important to note that the interfacial term breaks the mapping to a “standard” Cahn-Hilliard equation, in that there exist no free energy functional of which Eq. (2.17) is a functional derivative. Equivalently, the interfacial term breaks detailed balance.

Finally, we note that in Ref. \[50\] a repulsive term of the form

\[
f_{\text{rep}} = \omega \Theta(\rho - \rho_l)(\rho - \rho_l)^4
\]

is summed to \( f_0 \) to model excluded volume interactions, and to prevent the existence of a phase of infinite density. The repulsive free energy term is phenomenological, and it consists of constant \( \omega \) multiplied by the Heaviside step function \( \Theta \); there is also a density threshold \( \rho_l \) at which the repulsion is switched on.

To make calculations in practice with the continuum model in Eq. (2.16), an explicit expression for both \( v(\rho) \) and \( M(\rho) \) is needed. These require some information from microscopic theories, or simulations, which we will discuss next. Suffice here to say that, as shown in Ref. \[50\], an appropriate choice at low and intermediate densities is the following:

\[
v(\rho) = v_0 (1 - v_0 \sigma_s \tau_c \rho),
\]

(2.18)

for \( v(\rho) \), and

\[
M(\rho) = \frac{v^2(\rho) \rho \tau_c}{d(d-1)} = D_0 \rho (1 - v_0 \sigma_s \tau_c \rho)^2,
\]

(2.19)

for \( M(\rho) \). In the two equations above, \( \sigma_s \) is a scattering cross-section. This quantity is obtained by assuming that a single ABP trajectory consists of straight runs with speed \( v_0 \) punctuated by collisions lasting for a time \( \tau_c \) in which the particle arrests its motion.

In Fig. 1 we show intermediate-time snapshots of the concentration \( \phi = \rho/\rho_0 \) (where \( \rho_0 = (v_0 \sigma_s \tau_c)^{-1} \)) obtained by numerically solving Eq. (2.16) in 2D (left panel) and in 3D (middle and right panel) both at \( \phi_0 = 0.5 \) \[50, 71\]. Isolated domains of the dense phase in 2D (in yellow), clearly distinguished from the dilute phase (in blue), represent regions where particles tend to accumulate. Especially in 3D, the domain topology resembles one which is expected of phase separation in passive gas-liquid systems, or binary fluids.

It is quite a remarkable and striking feature that the model in Eq. (2.16), although almost fully built within the framework of equilibrium statistical thermodynamics \[7\], captures very well the existence and dynamics of motility-induced

\[\text{1}\] The weak transgression from equilibrium and detailed balance is the interfacial term, which has been extensively discussed in Ref. \[54\]. This has been shown to have limited impact on the physics of the system.
Figure 1: In this figure we report snapshots for the packing fraction $\phi = \rho / \rho_0$, with $\rho_0 = (v_o \sigma s_0)^{-1}$, obtained by numerically solving Eq. (2.16) in 2D (left panel) and in 3D (middle and right panel), both at $\phi_0 = 0.5$. The left panel shows a 2D projection of the corresponding 3D density field, whose isosurfaces are shown in the middle panel. More details about the mapping between $\phi$ and $\rho$ are described in Ref. [50].

phase separation, which is a far from equilibrium phenomenon. (Indeed, as we shall see more in detail in Section 3, Eq. (2.16) also reproduces well the dynamics observed in direct particle simulations of concentrated suspensions of active Brownian particles, with an enormously reduced computational cost [71].)

3. Motility-induced phase separation in self-propelled particle systems

In practice, both in simulations and in experiments, motility-induced phase separation has been observed in active brownian particles, rather than in run-and-tumble bacteria (recall that in ABPs rotational diffusion replaces tumbling, see Section 2). ABPs can be realised in practice, for instance, as synthetic (bi-)metallised colloids where some chemical reaction creates a self-phoretic local chemical motor [12, 13, 14, 15, 16, 17, 18]. An example of a motility-induced clusters observed experimentally in such systems is shown in Fig. 2. It is also relatively straightforward to set up a Brownian simulation of ABPs, and because this is the approach which has been the most commonly employed one in the study of MIPS, we focus in this Section on numerical work, reviewing first the model, then the phase diagram for MIPS, and later on the dynamics of MIPS in ABPs (Sections 3.1-3.2 describe simulations for spherical particles, 3.3 and 3.4 describe more general models for rodlike particles, or self-propelled particles with an alignment interaction).

In the simplest theoretical framework leading to MIPS, $N$ spherical ABPs interact each other only by excluded volume effects and are subject to a propulsive or active force continuously acting along a fixed polar axis for each particle. In a system with momentum conservation, as discussed later, the total force on a neutrally buoyant swimmer should instead be zero. However Brownian dynamics theories, e.g. simulations, neglect fluid-mediated interactions so the only way to propel a particle is to apply a force along its direction.
Figure 2: (a) An example of the dynamics of a cluster of active colloids. The particle marked by the black arrow (left snapshot) leaves the cluster and is substituted by another particle approaching (right snapshots). Red arrows denote the orientation of the caps. (b) The mechanism used by a particle for self-trapping is shown. After a collision, a particle becomes free when its orientation changes due to the rotational diffusion. This figure is taken from Ref. [55] where large enough Janus particles, allowing to visually resolve the single polarizations, are used.

This force is typically constant in modulus but its direction changes with time due to rotational diffusion. A minimal theoretical model with these characteristics is the following

\[ \dot{r}_i = \dot{\nu} i v_0 + \mu \sum_{j \neq i} F_{ij} + \eta_i^T , \]  

(3.1)

\[ \dot{\theta}_i = \eta_i. \]  

(3.2)

Here \( r_i \) are the coordinates of the center of mass of the particle \( i \) (\( i = 1, ..., N \)) and \( \mu \) is the mobility, while the polarity axis of each particle is defined by \( \hat{\nu}_i = (\cos \theta_i, \sin \theta_i) \), where the angle \( \theta_i \) is measured with respect to some fixed laboratory axis. Furthermore, \( v_0 \) is the fixed self-propulsion velocity and \( F_{ij} \) is the force due to the particle \( j \) acting on the particle \( i \) that takes into account excluded-volume steric effects. \( \eta_i^T(t) \) and \( \eta_i(t) \) are Gaussian, white noises with zero mean and correlations \(< \eta_i^T(t) \eta_j^T(t') >= 2D \delta_{ij} \delta(t-t') \) and \(< \eta_i(t) \eta_j(t') >= 2D_R \delta_{ij} \delta(t-t') \), where \( D = k_B T \mu \) and \( D_R \) respectively denote the brownian translational diffusion constant (\( T \) is the temperature of the bath) and the single particle rotational diffusion constant \( D_R = D/\sigma_c^2 \), with \( \sigma_c \) the diameter of the colloid (see e.g. [2] for a derivation).
The occurrence of phase separation in a realization of the above model was first shown in [47], and later confirmed and analysed in several works (which are reviewed later on). A nice feature of particle-based studies of MIPS, whether experimental or numerical, is that these allow a clear identification of the microscopic mechanism leading to the initial formation of clusters of self-propelled particles. In particular, one observes that when two or more particles collide head-on they are blocked due to the persistence of their orientations (see the experimental pictures in Fig. 2). A particle can escape from the cluster if, due to rotational diffusion, the direction of the polar axis changes so that the active force pushes away the particle from the cluster. This microscopic view is complementary to the macroscopic theory of MIPS, presented in Section 2.

Relevant adimensional numbers in terms of which the above model can be analyzed are the following. The surface fraction is given by

$$\phi = N \frac{S_c}{S} \quad (3.3)$$

with $S_c$ the area occupied by an individual colloid and $S$ the total area of the box where the particles move. Then we introduce the Péclet number, $Pe$, which is a dimensionless ratio between the advective transport rate and the diffusive transport rate. For particle flow one defines it as $Pe = L v / D$, with $L$ a typical length, $v$ a typical velocity, and $D$ a typical diffusion constant. We choose $L \rightarrow \sigma_c$, $v \rightarrow v_0$, and $D \rightarrow D = k_B T \mu$. Then,

$$Pe = \frac{\sigma_c v_0}{k_B T \mu} \quad (3.4)$$

3.1. Phase diagram

To begin our review of particle-based simulations of MIPS using the model described above, we discuss determinations of the phase diagram. From the considerations made above, and in Section 2, we expect that there should be a phase transition (MIPS) at low temperature or large self-propulsion (i.e. at large Péclet number) when the density of the system is sufficiently high. The phase diagram of a system of self-propelled disks is shown in Fig. 3. Here, the physical meaning of the red curve is similar to that of the coexistence curve in fluids with liquid-vapour transition. Outside the coexistence line, the system can only be in a single phase, while for Péclet numbers higher than a critical value and densities inside the coexistence curve, it phase separates into a gas phase and a particle-rich phase. An approximate analytical estimate for the phase diagram can be found in Ref. [60] – while the theory in Section 2 predicts phase separation, it disregards thermal diffusion so strictly works only for very large (actually infinite) Péclet number.

An interesting quantitative prediction of the phase diagram in Fig. 3 is that the critical point occurs for a value of the Péclet around 50, which can quite readily be realised with e.g. bacterial swimmers (the challenge though is to concentrate them up to $\phi_x \sim 0.6$, such that MIPS is predicted to occur in Fig. 3).

To determine numerically the coexistence curve one may, for instance, consider the probability distribution function $P$ of the local density $\phi_x$. This can
Figure 3: (Color online.) Phase diagram of a system of spherical ABPs (red curve), and of dumbbells (blue curve). Inside the curve, at high Péclet numbers, the system undergoes phase separation into two phases characterized by two different densities. Here, typically, large and stable clusters are observed, as shown in the snapshot for spherical ABPs on the right. In the case of dumbbells, these are frozen due to steric interactions and point preferentially towards the center of the cluster, while active colloids can still freely rotate inside the cluster. For small Péclet numbers the system does not show the formation of such large and stable clusters; a typical snapshot of the system in this uniform phase is also shown, again for spherical ABPs. The location of the transition line is based on the results of simulations fixing $v_0 = 0.1$ in both cases and varying $T$ (see [51, 52] for further details); the right snapshot is taken at $T = 0.01$, the one on the left at $T = 0.05$.

be obtained dividing the full system in cells with linear size larger (typically 10 times) than that of each particle and calculating the density in each cell. The size of the cells has to be much smaller than the linear size of the full sample and big enough to sample $\phi_x$ correctly. Then, letting the system evolve from an initial homogeneous configuration at a given total surface fraction, one can measure the distributions of local densities, $\rho$, in steady state.

An example of the analysis of these distribution functions, for a system of self-propelled disks is shown in Fig. 4 (the corresponding parameters are given in the caption). In each panel of this figure one observes that at low Péclet number the distribution is characterized by a single peak approximatively corresponding to the value of the total density while at high Péclet the distribution is characterized by the presence of two peaks which can be taken as the density values for the two coexisting phases. This can be shown to be a consistent procedure, e.g. by
checking that starting from a different total surface fraction the values of the two peaks remain the same [52, 72].

Figure 4: Phase density of the system at Péclet numbers given in the keys in the form \( \text{Pe}(T, v_0) \) for different temperatures, and \( v_0 = 0.01, 0.1 \). The global density of the system is \( \phi = 0.5 \).

3.2. Kinetics of phase separation

We now turn to the review of the studies of the kinetics of MIPS (these are less numerous in the literature). In analogy with the study of domain growth and coarsening in gas-liquid systems and binary fluid, the idea here is to measure the size of the phase separating domains (the particle-rich ones) \( L(t) \), for instance by taking appropriate moments of the structure factor [73]. The size of this domains then increases in time, and the analogy with Cahn-Hilliard models suggests that such a dynamics follows a power law,

\[
L(t) \sim t^\alpha,
\]

where \( \alpha \) is the exponent which measures how quickly coarsening proceeds. It is useful to recall here that the passive counterpart of the ABP model we are considering is a gas-liquid system in the absence of solvent-mediated hydrodynamic interactions – under these conditions one expects \( \alpha = 1/3 \) [73].

In their ABP simulations, Redner et al. [49], measured a growth of the cluster mean-size compatible with an exponent \( \alpha = 0.272 \). Stenhammar et al. [71], in a variant of the model of (3.1,3.2), performing more extensive simulations with \( 5 \times 10^5 \) particles, found \( \alpha = 0.28 \) in 2D systems. The same authors also performed 3D simulations with \( 4 \times 10^7 \) particles obtaining in this case \( \alpha = 0.34 \).

The previously mentioned power-law regimes were found after an initial transient with faster growth. It was observed in [71] that the cross-over to the final regime occurs when \( L(t) \) exceeded a persistence length related to the characteristic ballistic displacement of a single particle. This corresponds to the persistence length mentioned in Sect.2.2 and can be evaluated as \( l = v_0/D_R/(d - 1) \). Since this quantity is proportional to the Péclet number (it depends on the ratio \( v_0/T) \)
and phase separation occurs with $\text{Pe} > \text{Pe}_c$, it follows that very big systems are needed in order to have a large enough extension of the late time regime with reliable measurements. For example, in the simulations of [71], $\text{Pe}=300$ implies $l = 50\sigma$ so that a linear size $L_{\text{box}} = 350\sigma$ was considered leading to $4 \times 10^7$ particles in order to have $\phi = 0.5$.

In general, the results in both 2D and 3D are interpreted as consistent with the $\alpha = 1/3$ exponent, which is expected for very long times (such times are reached in 3D, but not in 2D due to the reasons just discussed). A natural question is whether the run-and-tumble particles previously discussed behave in the same way. In this area, the largest simulation to date is that in Ref. [74], which uses a lattice model of run-and-tumble particles and demonstrates that the “diffusive” exponent $\alpha = 1/3$ is found in simulations of MIPS in 2D.

![Graph 1](image1)

**Figure 5:** In this figure the length-scale $L(t)$ for the 2d (left snapshot) and the 3d (right snapshot) systems are shown. Both of them are obtained for packing-fraction $\phi_0 = 0.5$. The dashed lines gives the corresponding fitted exponents, which are: $\alpha_{2D} = 0.279$ and $\alpha_{3D} = 0.341$ for ABPs, $\alpha_{2D} = 0.287$, $\alpha_{3D} = 0.333$ for the continuum model with detailed balance violation. The blue curves represent $L(t)$ for the case in which the detailed balance is restored. The physics of this last case has been discussed in Ref. [54]. $\tau_r$ is the orientational relaxation time defined in Sect. 2.2. The dotted lines represent the persistence length which separate the region of superdiffusive behaviour ($\alpha > 1/3$) at short times from the region of diffusive behaviour ($\alpha \approx 1/3$). Figure is taken from Ref. [71], with permission.

### 3.3. MIPS with non-spherical particles: active dumbbells

Until now, we have focussed our review on the case of spherical self-propelled particles. In active matter physics, however a spherical shape as assumed in the previous section, is the exception rather than the rule. Swimmers, whether synthetic or natural, are often rod-like or elongated: this is true both of most bacteria, but also chemically propelled nanorods [3, 8, 75]. It is therefore of interest to analyse how MIPS is affected when the self-propelled particles have an elongated shape, i.e. they are rods, or dumbbells. In particular we will consider in this Section the case of active dumbbells.
In Ref. [29] a model of active dumbbells was introduced to describe the diffusive experimental behaviour of a bacterial bath coupled to colloidal tracers. Other simulations of rodlike active particles were presented in [59, 60, 61]: all these cases demonstrate that the physics of anisotropic active particle is richer than that of their isometric counterparts, for instance due to the possible onset of local orientational (nematic) ordering. To the best of our knowledge, the first analysis of the effect of shape anisotropy on MIPS was performed in [52]. In that work, the phase behaviour of active dumbbells of variable overall density and Pécel number was studied by means of Brownian dynamics simulations. The model of active dumbbells is a simple generalisation of those of ABPs; however, for dumbbells the rotational diffusion is no longer explicitly described as in Eq. (3.2), rather it effectively results from the net balance of forces on the two disks of each dumbbell (a detailed description of the model is given in [34]). Rotational and translational diffusion properties of active dumbbells have been studied in [34, 72].

The elongated shape of dumbbells leads to some important differences with to the case of spherical active particles. To begin with, phase separation is overall favoured in the case of dumbbells [52]. For instance, in Fig. 3 the coexistence curve for a dumbbell system can be compared with that of colloids; while the curves cross close to the critical point, for sufficiently large Pe the density range whether MIPS can be observed is larger for dumbbells.

However, by far the most striking feature about the dumbbell aggregates is that they exhibit coherent and long-lived vortex-like rotation (see Fig. 6). This coherent rotation is absent in the motility-induced clusters formed with spherical particles. On the other hand, we also observe that the clusters observed in the system of active rods of Ref. [76, 77, 60], where the length-to-width aspect ratio is larger compared with that of our dumbbells, show a translational motion but little detectable rotation.

What drives the self-organisation of rotating aggregates in systems of dumbbells? And why are they absent for spherical swimmers? A first explanation for the formation of such structures comes from considering torque balance on the droplets which form during MIPS. Within the Brownian dynamics simulations performed in [52], the forces exerted by each dumbbell add a local torque which is balanced by the drag on the cluster. While also spherical self-propelled particles would exert a local torque, this can only lead to rotational diffusion and not to sustained rotations, because the local swimming direction of each active particle can rotate freely within the cluster [49]. This is not the case for the dumbbell aggregates, where steric interactions essentially quench the polarisation of each of the dumbbells in the rotating droplet (see Fig. 6).

The overall coherent rotation of the cluster in Fig. 6 is apparent from a coarse grained plot of the dumbbell momentum field $\rho v$ (see Fig. 6 B), where $\rho$ and $v$ are the local density and velocity field of the dumbbells at a given point in space and instant in time. It can be seen that the topology of $\rho v$ is that of a vortex. Inspection of the local ordering within the high density rotating clusters of dumbbells also demonstrates that there is both nematic and hexatic order [52].
Figure 6: (A) Snapshot of a phase-separated active dumbbell fluid with three clusters (two of which are touching). The clusters, from the smallest to the largest one, contain about 4000, 12000, and 25000 dumbbells, respectively. The inset shows a detail of the dumbbell configuration; red and green beads indicate the tail and head of each dumbbell and are connected by a line. (B) Coarse-grained velocity field corresponding to the snapshot in (A), obtained by local averages on a square mesh. (C) Coarse-grained orientation profile of the dumbbell fluid (P̂), obtained by averaging as in (B), again corresponding to the configuration in (A). (D) Hexatic order parameter (computed as in Ref. [49]) corresponding to the configuration in (A) (defects, or grain boundaries, between ordered regions are observable). Figure is taken from Ref. [52].

The local director profile, measuring the average orientation of the dumbbells, P̂, shows a characteristic spiral pattern (Fig. 6C). A distinguishing aspect of the rotating aggregates in dumbbell systems is therefore that the velocity and orientational patterns are distinct: the former is a vortex, the latter a spiral. A minimal mean field framework to understand this fact was proposed in Ref. [52]: a conclusion from this theory is that a requirement in order for polarisation and velocity field not to be parallel to each other is that the theory should include a non-trivial momentum balance between self-propulsion and steric repulsion.
Computer simulations suggest that the velocity of the rotating clusters, $\Omega$, should depend on their radius, $R$. In particular, the Brownian dynamics simulations of Ref. [52] measure a scaling of $\Omega$ with $1/R$. This scaling can be understood by means of dimensional analysis as follows. First, we note that the torque on the cluster must be proportional to $R^3F_a$, where $F_a$ is the magnitude of the active force acting on each dumbbell, as the individual dumbbell torque is $\sim RF_a$, and given that the polarisation within the aggregate is coherent (interestingly, other arrangements, e.g. random, would lead to different scaling). Second, the rotational friction scales as the integral of $\dot{\gamma}r^2$, so as $R^4$. Balancing the two contributions leads to the observed $1/R$ scaling. It is interesting to highlight here that rotating clusters have been found in experiments with mixtures of bacteria and polymers, where bacteria feel an effective attractive interaction due to depletion attractions arising from the presence of the polymer [78]. In the experiments, again a $1/R$ behaviour of the angular velocity of the clusters is observed, however the details of the balance leading to this scaling are different. In Ref. [78], bacteria aggregate in 3D, the torque comes from bacteria at the surface of the cluster, and the drag on the cluster is Stokesian and $\sim R^3$. Furthermore, the rotating clusters found in Fig. 6 appear due to MIPS, whereas those in [78] due to an additional interparticle attraction (the depletion attraction).

While the work in Ref. [52] covers the effect of shape anisotropy on the MIPS phase diagram and cluster morphology, an interesting open question is to what extent and how shape may effect the kinetics of phase separation, e.g. the coarsening and growth laws of the domains.

3.4. Active particles with alignment interaction

The active dumbbells considered previously differ from spherical ABPs because their shape introduces an additional hydrodynamic variable, the local polarisation $P$. In this sense, active dumbbells can be viewed as a particular example of a more general class of self-propelled particles, which interact with each other through an alignment interaction. In the case of dumbbells, this interaction comes from steric effects alone, but in other cases it may have different origins: for instance bacterial swimmers may interact due to hydrodynamic interactions [3]. In this Section we briefly review the work done on MIPS for active particles with alignment interaction, originally presented in Ref. [79].

The starting point is arguably the best-known model for active particles, introduced by Vicsek et al. in 1995 [1]. This Vicsek model considers an ensemble of self-propelled particles which interact solely via an alignment interaction (whose origin is unspecified). The Vicsek model is defined by a set of rules, according to which particles move along the direction of their instantaneous velocity, and update their velocity to align it to that of their neighbours (defined for instance as the particles within a radius $R_0$ from the particle under consideration), adding some noise $\eta$. The Vicsek model exhibits a transition from an isotropic phase at large noise to a flocking state at low noise, where active particles move coherently [80]. This transition is a purely nonequilibrium phenomenon, and it provides an example of an order-disorder transition in 2D, which would be im-
possible (due to the Mermin-Wagner theorem) in an equilibrium system. The details of how exactly these rules are implemented are actually quite important in practice to characterise the statistical physics of the transition, but this is beyond the scope of our current work – the interested reader is referred e.g. to the comprehensive numerical discussion in Ref. [81]. For a review on different dynamical features in the Vicsek model one can see e.g Ref. [82].

While the original Vicsek model includes no interactions among particles except a rule which aligns their velocity, the continuum model presented in Ref. [79] presents a generalisation in which interactions among active particles are incorporated. The idea is that, very much in the spirit of Section 2 and in general of models of MIPS, steric interactions between particles can be effectively taken into account by postulating that the self-propulsion speed of each of the particles depends on the local density of the system (i.e. on the number of neighbours). The model considered in [79] is therefore a variant of the Vicsek model (dubbed the flying XY model) with a density-dependent individual speed for active particles. In practice, the model is defined on a box of size $L^2$ in which $N$ (pointlike) particles interact via a pairwise aligning forcing $F$. The position $x_i$ and the direction $\theta_i$ of the $i$th particle are governed by the following equations:

$$\dot{x}_i = v e_{\theta_i}; \dot{\theta}_i = \zeta \sum_{j=1}^{N} F(\theta_j - \theta_i, x_j - x_i) + \sqrt{2\epsilon} \eta_i(t).$$ (3.6)

Here $e_{\theta_i}$ is a vector corresponding to the direction $\theta_i$, $v$ is the self-propulsion velocity that depends on the number of particles $n$ in a given radius $R_n$ and has the form $v(n) = v_a e^{-\tilde{\omega} n} + v_b$, where $v_a \gg v_b > 0$ are the dilute and crowded limiting velocities and $\tilde{\omega}$ is a positive constant. Furthermore the constants $\zeta$ and $\epsilon$ control alignment of the particles and fluctuations, and $\eta(t)$ is a unit-variance Gaussian white-noise term.

A macroscopic description of the physics captured by this model can be obtained by coarse-graining the microscopic dynamics. This leads to the following continuum equations for the hydrodynamic fields, which are the density $\rho$ and $W = \rho P$, where $P$ is a vector field which gives the local alignment (polarisation),

$$\partial_t \rho = - \nabla \cdot (vW)$$ (3.7)

$$\partial_t W + \frac{\zeta}{16\epsilon} (W \cdot \nabla)(vW) = \left( \frac{1}{2} \zeta \rho - \epsilon \right) W - \frac{\zeta^2}{8\epsilon} W^2 W - \frac{1}{2} \nabla (v\rho)$$ (3.8)

$$+ \frac{3\zeta}{16\epsilon} \nabla (vW^2) - \frac{\zeta}{32\epsilon} v \nabla W^2 - \frac{3\zeta}{16\epsilon} W \nabla \cdot (vW)$$

$$- \frac{\zeta}{8\epsilon} v W (\nabla \cdot W) - \frac{\zeta}{8\epsilon} v W (\nabla \cdot \nabla W) + O(\nabla^2).$$

The former is the continuity equation for the density field $\rho$ whereas the latter is the evolution alignment for the “momentum” field $W$. The second term on the left-hand side of Eq. (3.8) describes self-advection of particles and the first two terms on the right-hand side take into account the standard spontaneous symmetry breaking from isotropic to polar order and flocking for sufficiently small $\epsilon$ in the
Vicsek model at $\omega = 0$. The third one is a pressure-like term which is responsible for the cluster instability when $\omega \neq 0$. Higher order terms on the left-hand side have been proved to have minor effect on the observed patterns [79].

The particle-based model in Eqs. (3.6), or the coarse-grained (hydrodynamic) continuum model of Eqs. (3.7)-(3.8) provide a minimal model where the Vicsek transition between an isotropic phase and an ordered flock is combined with MIPS. The resulting phase diagram, found by simulating either the particle-based model or the continuum one, shows that the interplay between these two nonequilibrium transitions creates a rich variety of possible patterns, which are reported in Fig. 7. Such patterns include flocking states, moving stripes or lanes and travelling clumps. Remarkably, the same patterns are found either in the microscopic model or in the coarse grained one (see Fig. 7). While some of the states are also close to the “flocks” or swarms reported in systems of rodlike active particles [59], it is notable that rotating spirals do not feature in the numerical solution of the equation, possibly because of the absence of a nontrivial momentum balance equation (in other words within this Vicsek-like model the velocity field and polarisation are identical, see discussion in Section 3.3). Another important open question in these models (either in the particle-based simulation or in the hydrodynamic theory) concerns the coarsening dynamics of the domains which form due to the motility-induced phase separation (equivalently due to the density-dependent propulsion speed).

4. Other aspects of motility-induced phase separations

4.1. MIPS with reproducing particles: arrest of coarsening

In Sections 2 and 3, we saw that the physics of motility-induced phase separation is akin to that of phase separation in a gas-liquid system, or in a binary mixture. This is because the clusters, which form when active particles bump into one another, coarsen, e.g. by Ostwald ripening – i.e. smaller aggregates evaporate to increase the size of larger clusters. In some cases, however, MIPS can also be arrested, so that clusters coarsen until a certain equilibrium size is reached, and no more. Here we consider one interesting example in which this happens: a population of reproducing run-and-tumble self-propelled particles whose velocity decreases with density [62].

A simple way to describe self-replication in bacterial colonies is to do so via a logistic growth law. This can be done naturally within our hydrodynamic framework, and leads to the following mean-field equation for the bacterial density,

$$\frac{\partial \rho}{\partial t} = \frac{\partial}{\partial x} \left[ D_{\text{eff}}(\rho) \frac{\partial \rho}{\partial x} \right] - k \partial_x^4 \rho + \alpha \rho \left( 1 - \frac{\rho}{\rho_0} \right),$$

(4.1)

where $\alpha$ is the growth rate (in s$^{-1}$), and $\rho_0$ is an equilibrium density which the bacteria tend to in the absence of other interactions. The value of $\alpha$ may vary greatly within bacterial colonies, between $0.6 - 0.8 \times 10^{-4}$ s$^{-1}$ for rapidly growing bacteria, to $0.1 - 1$ hr$^{-1}$, or even, less for slowly growing ones. The
Figure 7: Cluster configurations resulting from simulations of the microscopic (right column) and the continuum (left column) models described in Section 3.4. For other details, see [79]. Arrows denote the field $W$ and colors denotes the density field $\rho$. Red color indicates high values of $\rho$, yellow intermediate values and blue weak values. Several patterns are observed: (B) fluctuating flocking states, (C) stripes and (D) moving clumps.

Slowdown of swim speed with density can be driven either by quorum sensing between the microorganism, or to steric effects. The former is probably more likely in bacterial suspensions, as typically the equilibrium density that they would grow to, $\rho_0$, which sets a scale for typical values of $\rho$, is below 1%, at which it is unlikely that steric interactions play a major role.

Eq. 4.1 leads to an arrest of the phase separation introduced, due to the additional reproduction (and death) time scale which is set up by the logistic term, $\alpha \rho \left(1 - \frac{\rho}{\rho_0}\right)$. The mechanism leading to pattern formation and selection is
as follows. First, MIPS leads to the formation of clusters, or equivalently to an inverse diffusive flux which drives bacteria, or active particles, from dilute regions into particle-rich ones. This flux is counteracted by the logistic term, which tends to decrease the local density if it is above the target value $\rho_0$ (indeed $\rho \equiv \rho_0$ is the only stable solution for bacteria with a swim speed which is constant, or which decreases only mildly with density \cite{62}). The competition between these two terms lead to a steady state where the bacteria accumulate only to a certain point, and where multiple clusters coexist in steady state. One important finite length scale, which is to a good approximation related to the intercluster mean separation in steady state, is given by $\sqrt{D/\alpha}$, where $D$ is an effective diffusion constant (depending on the density imbalance between the particle-rich and the dilute phase). Only if $\alpha \to 0$ (no reproduction), coarsening can proceed indefinitely, corresponding to macroscopic phase separation discussed in Sections 2 and 3.

The resulting pattern depends strongly on the initial condition. For instance, starting from a uniform phase with noise leads to the formation of droplets, whereas starting from a bacterial droplet, or “inoculum” (i.e. with the density concentrated in a small region initially) leads to the formation of concentric ring or dot patterns, not unlike those which are usually associated with chemotactic bacteria \cite{63} (see Fig. 8).

![Figure 8: Patterns formed in a colony of self-reproducing bacteria with density dependent swim speed; reproduction and death are modelled by a logistic growth law. The initial condition was an inoculum (small bacterial droplet at the centre of the simulation box). Each row provides a series of snapshots observed for increasing time; the color refers to bacterial density (see colorbar on the right). More details on parameter values etc. are found in Ref. \cite{62}. Figure taken from \cite{62}, with permission.](image)

Interestingly, there are other experiments which suggests that, even with synthetic self-propelled particles, motility-induced phase separation results in separate clusters rather than in macroscopic phase separation \cite{56, 57, 58}. The
mechanism leading to arrest of coarsening under those conditions is still unclear.

4.2. The role of solvent-mediated hydrodynamic interactions

Up until now we have described models of “dry” active matter [9], i.e. where the solvent where active colloids typically move is neglected. In reality, microscopic swimmers (which move at low Reynolds numbers) stir the fluid they are in, hence they interact each other also through the solvent hydrodynamic flow field. This important fact, not considered in the previous Sections, can have relevant effects on the phase behavior. We will now briefly discuss this point in this Section.

There are different swimming mechanisms used by microorganisms, artificial active colloids and active droplets. Here we consider the most studied case of the so-called "squirmers" that propel themselves by a prescribed axisymmetric surface velocity field [83, 84]. They can be used as a simplified generic model for diffusiophoretic particles [16, 85], or for biological microswimmers where the action of cilia or flagella can be described at mesoscopic scales by the squirmer surface velocity field [83, 84]. A review on the role of hydrodynamics in the self-propulsion mechanisms is given in [86]. Here, we will focus on the effects of the hydrodynamic interactions on the collective behavior of squirmers and, in particular, on the possibility of having a (motility-induced) phase separation as in the cases discussed in the previous sections.

We first show in Fig. 9 the velocity field of different kinds of single squirmers. In order to describe different real microswimmers, the characteristic of the model can be varied to describe either pullers (equivalently contractile swimmers), with a vortex behind the body (Fig. 9(c),(f)), or pushers (equivalently extensile swimmers) with the vortex in front of the body (Fig. 9(a),(d)). Fig. 9 also shows the velocity field for the case of neutral swimmers. The velocity field associated with a moving puller or pusher is dipolar (the velocity of the solvent decays with distance from the swimmer, $r$, as $r^{-2}$), whereas that associated with a neutral swimmer is quadrupolar (the velocity decays as $r^{-3}$).

The simplest way to analyze the hydrodynamic interaction between squirmers is to consider the flow field around a pair of squirmers kept at fixed position [87]. In the case of pullers, as it appears clear from Fig. 9 the fluid is pressed into the region between the two squirmers increasing the pressure there, and leading to repulsion. On the other hand, in the case of pushers, the squirmers are expected to attract each other. An analytic expression for the force between two squirmers is available decaying with the inverse of the square of the distance between the squirmers, at large distances [88, 84]. However, other effects can combine with the main hydrodynamical interaction, rendering the dynamics of two squirmers more complex. For example, thermal fluctuations may play a relevant role [87]. Pushers initially oriented in parallel, allowed to swim freely, are observed to move towards each other but, due to diffusion, they do not always collide [87]. Sometimes, after collision, rotational diffusion reorients the squirmers and the trajectories diverge, with an increasing average spreading with decreasing Péclet number.
There are few studies of the collective behavior of squirmers. Simulations based on Stokesian dynamics \cite{89, 88} reported in \cite{64} showed that pullers are systematically more ordered than pusher spherical suspensions. In this work, order was measured in terms of the global polarization value coming from the average of the orientation vectors of all particles. In some way, this result contradicts the expectation based on the attractive (repulsive) character of the interaction between pushers (pullers). This behavior was attributed to a prevalence of head-to-head collisions favouring a faster decorrelation of pusher swimmers. The result was also shown to be independent on the initial, aligned or isotropic configuration, of the ensemble of particles. It also contrasts a prediction from continuum theories saying that an isotropic state is unstable only for nonspherical pushers \cite{90}. The number of particles considered in the simulations of \cite{64} was, however, too small in order to properly discuss the possibility of a phase transition.

A mixed simulation method, with a Lattice Boltzmann scheme for the fluid coupled to particle dynamics for the squirmers was considered in \cite{65}. Here the number of particles was much larger, few thousands, and the system was 3D. It was shown that pullers have a tendency to form transient aggregates. This was related to the presence of polar order, which occurs for pullers but in the case
of pushers. However, a macroscopic motility-induced phase separation was not observed. The origin of the polar order was attributed to a mechanism similar to that discussed in [64]. The aggregation phenomenon was shown to be almost absent in the case of pushers.

Using simulations methods similar to those of [64], it was shown in [66] that hydrodynamics should suppress phase separation for isometric squirmers in 2D; this was explained by mapping the model to a system of active particle in a range of parameters where motility-induced phase separation does not occur. In this work, most of the simulations were done with neutral swimmers (although simulations suggested that the results were similar for pushers or pullers).

The same squirmer system was considered in another recent work by Zöttl and Stark [67], that presents the results of simulations based on the multiparticle collisional dynamics method coupled to particle dynamics for the squirmers. The swimmers move between two walls, which allow both 2D translations and full 3D rotations. Unlike Ref. [66], this study found a pronounced difference in behaviour in the two cases. The main result of this work is that at sufficient high area fraction $\phi \geq 0.5$ the system can separate in a gaslike and a crystalline phase, depending on the nature of the swimmers. Pusher are observed to form a single cluster at $\phi \approx 0.65$ while pullers are observed to form several exagonal structures and a single cluster only at very high density. On the other hand, aggregation in clusters is seen to be greatly favoured for neutral swimmers and diminishes when the pusher character increases. These features are explained in terms of a strong enhancement of the rotational diffusion coefficient, compared with that of a single swimmer, due to hydrodynamic swimmer-swimmer and swimmer-wall interactions.

Finally, we mention the work in Ref. [91], which used a fluid-particle dynamics approach, and studied the effect of hydrodynamics on the collective dynamics of dumbbell swimmers with prescribed dipolar force pairs in 3D. This work showed that within semidilute suspensions of swimmers (in the presence of thermal fluctuations) hydrodynamic interactions appear to enhance the dynamic clustering (which can be seen as a precursor of fully-developed MIPS) at relatively small volume fractions. Within this model, this result arises due to hydrodynamic trapping of one swimmer by another, induced by the active forces. The final prediction of this model regarding MIPS is still pending. Preliminary simulations within this framework suggest that motility-induced phase separation should occur for sufficiently large propulsion forces (at a volume fractions of $0.2 \sim 0.25$); however the structure formed was not compact and exhibited large fluctuations, possibly because of the relatively small system size considered. A final assessment of the fate of MIPS in this model therefore requires even larger scale simulations.

As is clear from the above, gaining an ultimate understanding of the role of hydrodynamics interactions in motility-induced phase separation is a highly non-trivial, and still largely open question. This is due both to the fact that near field effects, which are difficult to capture accurately, seem to matter, and to the need to run very large scale simulations (as in the case of ABP [50, 54]) to come to a firm conclusion on phase separation in the bulk. In this sense, large scale
simulations in the future may hold the key to finding the answer to this difficult question.

5. Conclusions

In conclusion, we have reviewed here the physics and dynamics of motility-induced phase separation, a nonequilibrium phenomenon which occurs in a suspension of self-propelled active particles. Motility-induced phase separation was first predicted theoretically in [46] (a nice review on the topic, complementary to our work here, is the recent Ref. [92]). The physics underlying this phenomenon can be understood as follows. Imagine that due to a fluctuation the density of the suspension increases locally: because self-propelled particles (unlike Brownian colloidal particles) accumulate where they are slow (see Section 2 and Refs. therein), then this fluctuation can trigger a positive feedback loop whereby particles accumulate further, slow down even more etc, eventually resulting in macroscopic phase separation, at least for suitable values of the density and propulsion speed (or Péclet number). Microscopically, the formation of dense regions can be traced down to the self-trapping of active particles, which move much faster than their diffusion, hence bump into each other to form clusters from which they cannot easily escape.

The physics and dynamics of motility-induced phase separation shares several aspects with that of gas-liquid systems, or binary mixtures. Importantly, the baseline model predicts that the particle-rich domains should coarsen, with a growth law which is compatible with that of a diffusive Cahn-Hilliard equation, both in 2D and 3D. This conclusion is gained, for instance, from an analysis of very large scale Brownian dynamics simulations of spherical active Brownian particles, and is also confirmed in 2D lattice simulations of run-and-tumble particles. We have also seen that the phenomenology of motility-induced phase separation has some importance differences when considering elongated particles, such as dumbbells. Here, particle-based simulations show that the aggregates which form due to the self-trapping mechanism rotate coherently, and we have seen how the dependence of angular velocity on cluster size can be understood with simple scaling arguments.

Importantly, coarsening can be arrested; an intriguing example is provided by a population of reproducing run-and-tumble with a density-dependent swim speed, which would lead, in the absence of reproduction, to macroscopic phase separation. The presence of an additional time scale, linked to reproduction and death of bacteria, which can be, for instance, captured by a simple logistic law, allows phase separation to be arrested. The resulting patterns are very similar to those found in bacterial colonies growing in semisolid media, such as agarose gel. Such patterns were normally attributed to chemotaxis; the results in Section 4 suggest that arrested motility-induced phase separation provides another viable mechanism for these clusters.

There are several open questions which are needed to fully understand motility-induced phase separation, and we have mentioned some of these in our work.
First, it is unclear to what extent the diffusive scaling exhibited by spherical self-propelled particles, and the associated continuum theory, applies to suspensions of anisometric active particles, such as dumbbells or rods. Second, a few of the experiments studying the phase behaviour of self-propelled particles \cite{57, 93} seem to be consistent with arrested phase separation. The possibly mechanism leading to arrest of coarsening in this context is unclear at the moment. Third, the role of solvent-mediated hydrodynamic interactions are currently not fully understood; yet the simulations performed to date suggest that they are likely to affect the physics of motility-induced phase separation significantly. We hope that our review will stimulate further work on this interesting nonequilibrium phase transition in active matter.
